ANCIENT DUNES AND PALEOSOLS OF THE SAHEL AND SAHARA IN EAST NIGER AS ARCHIVES OF PLEISTOCENE AND HOLOCENE CLIMATE CHANGES

Felix-Henningsen Peter*^[1]

^[1]Justus Liebig University ~ Institute of Soil Science and Soil Conservation ~ Giessen ~ Germany

Fossil and relict paleosols found in extremely arid to semiarid climatic regions of the Sahara desert can provide evidence of past humid climatic periods. These soils developed in eolian sands and can be used to indicate dry climatic phases that occurred prior to humid periods. Three generations of ancient dunes with paleosols were found along a SW-NE traverse covering 20 study sites from the southern Sahel of East Niger to the Ténéré desert and Tchigai mountainous region, and up to the southern border of Libya. OSL dating revealed that the accumulation of Upper Pleistocene ancient dunes began at 29.3 BP and ended at 9.5 BP. A second dune generation, in NE Niger mainly preserved in the wind shadow positions of escarpments and inselbergs, developed under arid conditions with an end in dune sedimentation between 5.2 and 3.5 ka. Paleosols on these dunes indicate a further humid period after 3.5 ka. During this humid period, weak Cambisols also developed on the younger dune generation. The continuously increasing aridity during Upper Holocene found a maximum at about 1.2 – 1.8 ka, indicated by the sedimentation of a further area-wide dune generation in NE Niger. The dunes in the Central Sahara were stabilized by weak weathering and covered by rock debris in a subsequent humid interval of short (possibly only several 10 - 100 a) duration.

LATE PLEISTOCENE-HOLOCENE TEPHRA AND VOLCANIC SOILS IN THE VESUVIUS FOOTHILL, SOUTHERN ITALY: RECONSTRUCTION OF TIME SPANS OF SOIL FORMATION AND CLIMATIC CHANGES

Scarciglia Fabio^[1], Zumpano Veronica^[1], Sulpizio Roberto^[2], Terribile Fabio^[3], Pulice Iolanda^[1]

^[1]Università della Calabria ~ Dipartimento di Scienze della Terra ~ Arcavacata di Rende (CS) ~ Italy ^[2]Università di Bari ~ Dipartimento Geomineralogico ~ Bari ~ Italy ^[3]Università di Napoli "Federico II" ~ DISSPAPA ~ Portici (NA) ~ Italy

In this work we present the main results of a multidisciplinary study of late Pleistocene to mid-Holocene primary tephra and interlayered volcanic soils as indicators of terrestrial ecosystem responses to late Quaternary climatic changes. We focused on a pedostratigraphic succession of soils developed on and/or buried by well-known volcanic layers of different ages, sourced from the Somma-Vesuvius volcano (Campania region, southern Italy). Five tephra give detailed chronological constraints to the stratigraphic record: the Pomici di Base tephron at the bottom (22 ka BP), followed upward by the Pomici Verdoline (19 ka BP), the Agnano Pomici Principali (APP) (12.26 ka BP), the Mercato (8.9 ka BP) and Avellino eruption (3.9 ka BP) pumice deposits at the top. Four pedons interlayered between each subsequent couple of tephra were studied in detail in terms of physical, chemical, mineralogical and micromorphological features, with special emphasis on (i) reconstructing dominant pedogenetic processes and corresponding (paleo)environmental/climatic conditions, along with (iii) degree of soil development and associated time spans. SEM-EDS analyses performed on two further tephra identified within two of above pedons but up to now unknown in the Vesuvius stratigraphy (referred to the Soccavo 4-5 and the Tufi Biancastri eruptions from the near Phlegrean Fields) permitted to fix further age constraints for more detailed assessment of rates of soil formation. Major climatic phases coherent with Last Glacial Maximum to Lateglacial and early- mid-Holocene climatic optimum are evidenced by varying degree of expression of andic properties, soil microstructure, carbonate accumulation, iron-oxide staining and silt-clay illuviation.

Soils having a morphology of typical Podzols, e.g. whitish eluvial horizon over a dark brown illuvial horizon, are widely extended in the upper forest zone of the Sudety Mountains, on granite, gneiss, and sandstone saprolites. Large differences in organic matter and iron/aluminium content was found among E and B horizons, followed by contrasts in base saturation, macro- and microelement concentrations etc. However, an arrangement of skeletal fragments is variable in the successive horizons of soil profile indicating a slope cover-bed to be a proper parent material rather than the homogenous saprolite. E and B horizons differ in soil texture (mostly sand over loam) and in both, the content and distribution of heavy minerals in a sand fraction. Moreover, plant pollen spectra in Bh and A (or AE) horizons differ significantly, indicating an influence of various, but always a Holocene vegetation. It was concluded finally, based on above mentioned arguments and soil micromorphology, that present-day Bh horizons are in many cases the former surface horizons ABw buried under a cover sand (or loamy-silty sand) layer. These cover-beds do not meet a German model of periglacial (Pleistocene) cover series due to the lack of an eolian silt addition or layer. The sand covering the soils under study is of local origin, however, the conditions and process of sand layer formation are not fully understood and still under discussion.

IDENTIFICATION AND QUANTIFICATION OF POSTSEDIMENTARY ROOT-DERIVED OM IN LOESS-PALEOSOL SEQUENCES USING LIPID MOLECULAR PROXIES

Gocke Martina^[1], Wiesenberg Guido L.b.^[1]

^[1]University of Bayreuth ~ Department of Agroecosystem Research ~ Bayreuth ~ Germany

Loess-paleosol sequences are one of the most important terrestrial archives for studying paleoenvironmental conditions. Initial organic matter (OM) in loess is supposed to derive from aboveground biomass of vegetation prevailing during loess deposition. Recent studies show, however, that significant portions of loess OM can derive from roots and associated microbial biomass, entailing uncertainties for paleoenvironmental research. This study aims to decipher the effect of postsedimentary deep-rooting plants on original composition of loess OM, as well as its extent. Calcification of roots, leading to formation of rhizoliths, entails improved preservation of root and rhizomicroorganism remains accumulated during the lifespan of former roots. At Nussloch (SW Germany), rhizoliths, surrounding loess (rhizoloess) up to a distance of 10 cm and root-free loess were sampled at different depths and analysed for Corg and lipid composition. Molecular proxies of alkane and fatty acid (FA) fractions argue for the presence of root and rhizomicroorganism derived OM in the vicinity of rhizoliths. High amounts of strongly degraded and microbial biomass, resulting in low average chain length and carbon preference index of alkanes and FAs in rhizoloess, suggested the presence of a former rhizosphere. Mono- and polyunsaturated FAs as indicators for microbial and plant biomass, as well as di-carboxylic acids as root-specific markers were used to quantify postsedimentary incorporated OM in loess. Several proxies suggest an extension of the former rhizosphere of at least 8 cm. Due to the high rhizolith abundance at Nussloch (up to 190 m⁻²), significant overprint of loess OM can be expected.

S01.01a -5

**SOIL WEATHERING AND ACCUMULATION RATES OF POORLY CRYSTALLINE PHASES
DERIVED FROM A 1MA CHRONOSEQUENCE**

Egli Markus^[1], Dahms Dennis^[2]

^[1]University of Zürich ~ Dept. of Geography ~ Zürich ~ Switzerland ^[2]University of Northern Iowa ~ Department of Geography ~ Cedar Falls ~ United States

In this study we compare published and new weathering data from soils developed along chronosequences of glacial deposits of the European Alps and the Rocky Mountains (Wind River Range, USA). This procedure enabled us to present comprehensive datasets over a time period of >1 Ma. We describe weathering of main elements using several weathering indices such as the (K+Ca)/Ti ratio, the weathering index B of Kronberg and Nesbitt and the open mass transport function. In addition, we show the accumulation of Al, Fe, Si and Mn oxyhydroxides as a function of time and derive the corresponding accumulation rates. The pedogenetically formed oxyhydroxides were calculated using an approach based on immobile elements. For one of the first times, overall formation rates of these phases can be plotted as a function of soil age (up to 1 Ma). These formation rates distinctly decreased with increasing age of the soil. After 1 Ma, about four order of magnitudes lower rates were determined. The datasets suggest that the older soils may be reaching a steady state for these chemical properties in their present environments. The decrease of the accumulation rate is not only influenced by the factor Time but also by the factor Climate (higher precipitation rates lead to a slower rate decrease). A power function (index B, (K+Ca)/Ti) or an 'exponential decay model function' (accumulation of pedogenetically formed weakly and poorly crystalline phases, relative losses using the open-system mass transport function) best explained the measured trends.

Smouldering is a flameless form of combustion, deriving its heat from heterogeneous oxidation on the porous surface of a solid fuel. Smouldering fires of peatlands represent a large perturbation of the atmospheric chemistry; when active, the burning of ground layers can last for long periods of time (months or years). The propagation depth depends on moisture and inert content of the peat. Most studies on smouldering to date focused on ignition, C losses or emissions, but the literature still lacks understanding of the evolution of organic matter (OM) following smouldering fires. This topic is extremely important especially for paleoenvironmental reconstructions, because peat soils are often used as natural archives of climatic and vegetational changes reaching. For example, previous studies have generally interpreted peaks in ash content as ascribed to an increase of either dust depositions or mineralization, whereas variations in C/N to changes in either vegetational or humification degrees. The present work proposes that these could be signatures of ancient peat fires. In particular, we show preliminary data about changes in OM features along three Sphagnum peat columns (25cm deep) having different initial moisture contents (MC): 50%MC, 100%MC, and 200%MC. Results underlined significant variations in terms of ash content, pH, elemental composition, main atomic ratios (C/N, C/H, O/C) and spectroscopic features across the interface between burn residue and undisturbed peat. At the same time, some of observed trends (e.g., TC, TN, C/N and C/H) were quite reproducible in the experiments, thus suggesting some "proxies" to reconstruct ancient smouldering events.

BRANCHED TETRAETHER LIPIDS IN A FRENCH PEATLAND : APPLICATION TO THE RECONSTRUCTION OF PAST TEMPERATURES AND PH

Huguet Arnaud^[1], Fosse Céline^[2], Laggoun-Défarge Fatima^[3], Derenne Sylvie^[1]

^[1]BioEMCo ~ CNRS/UPMC UMR 7618 ~ Paris ~ France ^[2]Chimie ParisTech (ENSCP) ~ Laboratoire de Spectrométrie de masse ~ Paris ~ France ^[3]Institut des Sciences de la Terre d'Orléans ~ Université d'Orléans/CNRS ~ Orléans ~ France

Over the last years, branched glycerol dialkyl glycerol tetraethers (GDGTs) were increasingly used for the reconstruction of past air temperatures and soil pH through the application of the MBT /CBT proxies (methylation and cyclisation ratio of branched GDGTs). Nevertheless, only a few studies were interested in the application of these proxies in peatlands. In this work, the applicability of the MBT/CBT in peat was examined by analyzing branched GDGTs in a 4 m peat core collected in the French Jura Mountains and covering the last 6 000 years. Branched GDGTs present as core (CLs; derived from dead biomass) and intact polar lipids (IPLs; markers for living cells) were analyzed. A significant proportion of GDGTs was derived from extant biomass (ca. 20-30%) in both the top and down parts of the bog. The MBT/CBT proxies were shown to overestimate temperature and pH. Thus, in the top part of the bog, MBT/CBT-derived temperature (ca. 10 °C) was higher than measured annual air temperature (ca. 6°C) and was more consistent with spring and summer temperature, suggesting that branched GDGT-producing bacteria might be more active during the warmest months of the year. At 2.5 m depth, reconstructed temperature and pH showed a pronounced shift, likely reflecting both a change in the composition of the peat and in climatic conditions. Interestingly, CBT-derived and measured pH records showed similar variations with depth. Our data suggest that, as shown in other environments, a specific calibration is required to apply the MBT/CBT proxies with confidence in peat.

Centuries of human influence have led to large scale reduction of montane forests in the northern Ecuadorian Andes. As a result the natural position of the upper forest line in the area is now subject of scientific debate, which is hindering sustainable reforestation efforts. Uncertainty is fuelled by insufficient precision of fossil pollen spectra to reconstruct the natural upper forest line position. We recently developed the Vegetation Reconstruction Helped by Inverse modelling and Biomarkers (VERHIB) model; a biomarker application based on plant species specific patterns of n-alkanes and n-alcohols preserved in sediments in chronological order. The model unravels the mixed biomarker signal into the plant species composition. We used the new biomarker application to reconstruct past vegetation patterns from several soil profiles in the Guandera Biological Reserve in the northern Ecuadorian Andes. Changes in biomarker-based vegetation composition in the last 3500 yrs BP were directly compared to changes in pollen-based vegetation composition from the same profiles. Both proxies proved to be highly complementary and allowed for reconstructions of past vegetation change with great detail. We found that the upper forest line in the study area has not been significantly depressed by human interference and was at 3650 m maximally during Holocene times. The combined pollen-biomarker approach in soil profiles theoretically allows for an unlimited number of reconstructions to be made along an altitudinal transect, and is not dependent on the presence of peat archives in depressions in the landscape.

Ombrotrophic peat bogs represent reliable archives for the atmospheric deposition of several elements. Furthermore, since mosses have a high interception potential for aerosols in precipitation, peat bogs may exhibit enrichment in fallout elements and radionuclides such as ^{210}Pb , ^{210}Po , ^{236}U and plutonium isotopes. The ^{210}Pb method is widely used for dating peats and sediment layers. The obtained ^{210}Pb depth profiles are usually compared with independent chronological markers, such as the ^{137}Cs activity. However, ^{137}Cs derived data may be not reliable since caesium shows post-depositional mobility in reducing environments. In this contribution, the use of $^{236}\text{U}/^{238}\text{U}$ and $^{240}\text{Pu}/^{239}\text{Pu}$ isotopic ratios as complementary time markers is evaluated. For this, characteristic isotopic composition related to global fallout from the atmospheric weapons tests (with maximum in 1963) and the Chernobyl accident (1986) can be used. This concept is applied to an undisturbed ombrotrophic peat core collected at the Northern Black Forest, Germany.

^[1]University of Turin ~ DiVaPRA - Agricultural Chemistry and Pedology ~ Turin ~ Italy ^[2]University of Perugia ~ Department of Agricultural and Environmental Science ~ Perugia ~ Italy

Soil fertility and C stocks of anthropogenic soils formed during land reclamation activities may be enhanced by amendment with municipal waste compost (MWC). Although the positive effects of compost application to arable soils is well recognized, little is known on how land rehabilitation practices effect C dynamics in such relatively young soil systems. Within the framework of a long-term experiment, this work aims at evaluating temporal and spatial dynamics of compost-derived organic matter (OM) with respect to the major processes involved in OM cycling in an anthropogenic landfill covering soil amended with MWC. We investigated long-term C dynamics in such systems by collecting landfill covering soil samples at different depths, from a 10 year chronosequence. Compost application enhanced the C stocks of amended topsoils, and $\delta^{13}C$ values showed that compost-derived organic matter was distributed throughout the soil profile. The addition of compost to the superficial layer resulted in a significant input of soluble organic compounds subject to leaching. Sorption isotherms for compost-derived water-extractable OM onto mineral materials used for landfill covering as well as the accumulation of lignin-derived phenolic biomarkers suggest that sorptive preservation contributed to increasing C content of deeper soil horizons with time. Nevertheless, changes in the content of non-cellulosic carbohydrates in soils and their respective water-extractable fractions suggest that a proportion of compost-derived, labile organic matter fraction is leached through the soil profile and potentially lost from the soil system, particularly in the years immediately after compost application.

^[1]Nancy-Université / INRA ~ Laboratoire Sols et Environnement ~ Vandoeuvre-Lés-Nancy ~ France

Constructed soils are Technosols resulting from the deliberate combination of various technogenic materials to restore derelict lands. The efficiency of the brownfield reclamation relies on the sustainability of the constructed Technosols and therefore requires studying their early pedogenesis. The present work focuses on the evolution of their structure at different scales. Two soils were constructed in lysimetric plots (10 x 10m x 1 m depth), using a soil engineering process by the association of paper-mill sludge, thermally treated soil material, and green-waste compost. The evolution of the soil profiles was studied in situ for 3 years. It consisted in the confrontation of i) the observation and description of the macro-structure organization, ii) the texture, iii) the stability of aggregates, iv) indirect measurement of the porosity thanks to pressure-plate methods and v) observation at ultrastructural scale of 0-50 μ m organo-mineral fractions. The first result is the horization of both soil profiles with the differentiation of the initial layers in new soil horizons. Then, the structure of the soils evolved by global compaction and by the change of the porosity distribution. At a smaller scale, mechanical and biological aggregates formation was described and an increase of the aggregate stability with time was measured. Intrinsic reasons relating to the technogenic parent materials origins inevitably induce a remarkable intensity in the pedogenic processes of constructed Technosols. Disequilibria between the parent materials and the environmental forcing factors lead to a fast and original pedogenesis, certainly peculiar to Technosols.

Since Dokuchaev Russian plain is known as a classic model of bioclimatic zonal soil sequence. But soil geographic pattern correlates also to glacial history where earlier glaciations were more extensive than most recent one. Three conspicuous belts follow the pattern of glacial and periglacial sediments and corresponding paleocryogenic and relic soil features. The area south of Late Saalian limits is characterized by extensive loess mantles. Polygenetic features in Faeozomes and Chernozems are determined by loess stratification, marked by paleocryogenesis, paleohydromorphism and relic soil features (i.e. buried humus horizons). An area within Late Saalian limits is characterized by a diverse set of sediments (separate bodies of loess, glacial till, fluvioglacial sand, etc.) as a result of complex glacio-dynamic structure of cover glacier and high dissection of relief. The key to understanding relic soil features is the fact that day surfaces on different types of relief are heterochronous. The E/Bt horizonation of Glossisols and Luvisols on loess and glacial till is largely inherited from stratified sediments. Within Weichselian limits high flooding prevented extensive loess accumulation. Soils inherited specific layering of sediments (laminated clays, fluvioglacial sands and glacial till with veneer of fluvial sand; on higher ground till with thin veneer of cover sand, sometimes of loess; etc.). Relic features in relation to glacial history need to be further investigated. On glacial and periglacial plains they allow re-evaluating not only soil genetic models but zonal soil pattern, with bioclimatic gradient being superimposed on zonal sequence of sediments and paleocryogenic features.

WETLAND, FLOODPLAIN, RIPARIAN SOILS: THE EFFECT OF NITROGEN LOADING ON THEIR ECOLOGICAL FUNCTIONS.

Hefting Mariet*^[1]

^[1]Utrecht University ~ Biology ~ Utrecht ~ Netherlands

Due to their position at the interface between terrestrial and aquatic ecosystems, riparian zones are hot-spots for biogeochemical cycling and are at the same time of crucial importance to conserve biodiversity. However, there is concern about enhanced greenhouse gas emissions, reduced carbon sequestration and loss of biodiversity, where riparian zones have become overloaded with N-rich surface water or groundwater. This paper gives a general overview of nitrogen loading effects on the ecological functions of riparian areas. We studied denitrification activity and N₂O emissions from riparian zones and floodplains at different stream orders assuming that increased connectivity between N-loaded stream water and floodplain would lead to a significant increase in denitrification activity and N₂O emission. Results demonstrate that significant N₂O emissions were restricted to soils with pH values below 5, mostly occurring in stream headwater areas only. Locally, denitrification and N₂O emissions are also extremely variable showing a hotspot pattern. We used a hotspot-coldspot approach, to identify the driving forces of these hotspots. Soil incubations showed N₂O emissions from hotspots are caused by reduced N₂O consumption, mainly in acidic soils. The effect of N-loads on soil carbon sequestration tested in fertilised riparian soils in a geothermally heated riparian wetland in Iceland. This study provides evidence that interaction effects between N-loading and global warming maintain the carbon storage in wetland soils due to suppressed decomposition of SOC. Finally N-effects on biodiversity will be illustrated with results from long-term fertilisation experiments in floodplains and preliminary results of flooding and drought experiments

PROPERTIES, CLASSIFICATION, AND DYNAMICS OF FLOODPLAIN SOILS

Rinklebe Jörg*^[1]

^[1]University of Wuppertal ~ D, Soil- and Groundwater-Management ~ Wuppertal ~ Germany

In comparison to terrestrial soils floodplain soils are less studied. They are influenced by groundwater, static water, return seepage, and flood water. Based on our 15 years experiences with soils along various rivers in Germany this presentation will provide a detailed insight into the properties and dynamics of floodplain soils. Thereby the spatial distribution of floodplain soils in the landscape, typical soil profiles, their classification and characteristics will be demonstrate. Particularly we will emphasize the dynamics of those soils with view to the water level, soil matrix potential (?), temperature, redox potential (EH), and pH as well as matter fluxes such as dissolved organic carbon (DOC), Fe²⁺, NO₃⁻, PO₄³⁻, SO₄²⁻, and trace metals. To monitor those parameters in a high temporal resolution we have used well-equipped soil-hydrological monitoring stations in the field. Additionally, a new approach for a specific floodplain soil classification system based on objective, measurable soil parameters will be presented. For the first time the soil classification and empirically derived grouping according to the German Soil Classification have been statistically proved. The Canonical Discriminant Analysis (CDA) as an innovative multivariate statistical procedure has been used for this purpose. Floodplain soils can be distinguished by using CDA and they can be predicted by using β -glucosidase activity, total titanium, nickel, zinc and iron levels as well as protease activity. Our approach is potentially suitable for developing a soil classification system based on measurable parameters what has direct implications for soil mapping and the implementation of practical soil research findings.

AGGREGATE FORMATION IN RIPARIAN SOILS

Graf Markus*^[1], Friederike Lang^[1]

^[1]Berlin Institute of Technology ~ Department of Soil Science ~ Berlin ~ Germany

The sequestration potential of riparian soils for organic carbon is in the centre of recent discussions. Up to now, knowledge on aggregate formation and associated stabilisation of organic matter by aggregate-occlusion in riparian soils is lacking. Aim of our study is to analyse the influence of sedimentation dynamics on the architecture of aggregates and the content of occluded soil organic matter (SOM). We analysed the mobilisation of SOM due to sequential aggregate disruption by ultrasound application from soil samples and freshly deposited sediments taken at various sites of a floodplain of the Danube River near Vienna, Austria. In addition, SEM imaging was used to characterise the aggregates. In soils developed under dynamic sedimentation conditions, which are characterised by periods without any sedimentation, more SOM is stabilised within aggregates than in freshly deposited sediment. Furthermore, hierarchically constituted aggregates are formed with progressing soil formation. Static sedimentation conditions (characterised by continuous flooding) obviously impair the formation of hierarchical aggregate structure and the occlusion of SOM, even though the sediment deposited on these sites consists of hierarchical structured aggregates. In soils which were not subjected to flooding since 120 years (but show similar properties than soils of static sites) hierarchical aggregates are formed and show slightly increased amounts of SOM stabilised by occlusion. Summarising, our results indicate that flooding and input of sediment interfere with the development of aggregates with hierarchical structure. The influence of aggregate architecture on SOM stabilisation is subject of ongoing experiments.

NITRATE LEACHING FROM SHORT-HYDROPERIOD FLOODPLAIN SOILS

Benjamin Huber^[1], Luster Jörg^[1], Stefano M Bernasconi^[2], Juna Shrestha^[1], Graf Pannatier Elisabeth^{*[1]}

^[1]Swiss Federal Institute for Forest, Snow and Landscape Research WSL ~ Forest soils and Biogeochemistry ~ Birmensdorf ~ Switzerland ^[2]ETHZ ~ Geological Institute ~ Zurich ~ Switzerland

Numerous studies have shown the importance of riparian zones to reduce nitrate contamination coming from adjacent agriculture lands. However, most of these studies were performed in floodplains with long-hydroperiods (week to months of inundation) or permanently inundated water bodies with strongly reducing conditions, facilitating nitrate removal. Much less is known about nitrogen (N) transformation in riparian soils with short-hydroperiods (1-3 days of inundation). In this study, we measured nitrate concentrations in soil solutions in three succession vegetation zones (grass, willow bush and mixed forest) within a restored section of the Thur River in NE Switzerland. We quantified input (atmospheric deposition and sedimentation) and output (leaching) of nitrogen in the three zones to assess the N balance and the risk of nitrate leaching from the unsaturated soil to groundwater. Our results lead to the following conceptual model: in early successional stages (grass and willow bush), the dominant process is N sedimentation increasing the self-cleaning capacity of the river (N sink). With increasing distance from the river, in the mature mixed forest, soils are less hydrologically linked to the river and N sedimentation is reduced. Depending on soil type (low C/N ratio, high clay content) and soil environmental conditions (soil moisture at field capacity), high amounts of nitrogen are released by mineralization of organic matter accumulated in earlier successional stages and by subsequent nitrification. As a consequence nitrate leaching from the unsaturated zone into groundwater occurs (N source) and can lead to significant nitrate contribution during flood events and in winter.

FOOD WEBS AND ECOSYSTEM SERVICES IN CALIFORNIA RIPARIAN OAK WOODLANDS

Hodson Amanda*^[1], Jackson Louise^[1], Ferris Howard^[1]

^[1]University of California Davis ~ Land Air Water Resources ~ Davis ~ United States

The structure and complexity of riparian soil food webs in California can decline with increasing agricultural intensification, causing corresponding decreases in nitrogen retention and carbon sequestration. We explored undisturbed riparian soils for complex soil food webs and assessed indicators of associated ecosystem functions on a nature reserve near the ecotone where the Central Valley and Coast Range merge. To examine ecological patterns of soil biodiversity, nematode communities were used as indicators of the complexity of the soil food web, and were related to plant communities and indicators of ecosystem functions such as carbon storage and soil nutrient loading. Metabolic footprints, based on the size-dependent metabolic costs of different functional guilds of nematodes, were calculated to estimate their activity and potential role in ecological processes. Woody shrubs in these riparian ecosystems harbored particularly high levels of fungal feeding and bacterial nematodes, suggesting a role of biodiversity in the provision of ecosystem services for regulating soil and water quality.

SOIL BIOTA AND ECOLOGICAL PROCESSES IN RIPARIAN HABITATS

Chauvat Matthieu^[1], Chockri Mchergui^[1], Fabrice Bureau^[1], Estelle Langlois^[1]

^[1]University of Rouen ~ Ecodiv EA 1293 - FED SCALE ~ Rouen ~ France

Riparian habitats are among the most ecologically important systems, not only in terms of their intrinsic conservation value, but also because of the ecosystem goods and services that they provide (the regulation of hydrologic fluxes, maintenance of water quality...). Therefore, one goal of present rehabilitation measures along large lowland rivers is to reinstate and improve the natural dynamics of river banks which has very often been strongly impaired by river regulation. However, few studies have focused on soil biodiversity in such systems, despite their fundamental in controlling soil ecological processes. In riparian habitats inundation is an iterative and irregular phenomena. It represents a natural disturbance for the soil biocoenoses, causing their successional development to be completely or partially reset until the next flooding event. Along the Seine River in France and close to the estuary, soil biota assemblages and ecological processes were spatially described from a mudflat until an alluvial forest according to a gradient of flooding duration. Results showed a higher species diversity in the intermediate inundation duration compared to both lower and higher topographical habitats. Our results fit the intermediate disturbance hypothesis. This model predicts that at some intermediate level of disturbance species richness will be maximum mainly because an intermediate degree of disturbance reduces the intensity of competition between species and hence the competitive exclusion of species. Furthermore, relationships between soil biota assemblages and ecological processes were depicted at different scales highlighting to need to take into account the belowground system when measuring ecosystem services.

CANADIAN PEATLANDS AND THEIR ROLE IN CLIMATE CHANGE

Tarnocai Charles*^[1]

^[1]Agriculture and Agri-Food Canada ~ Research Branch ~ Ottawa ~ Canada

Peatlands in Canada cover about 1136 x 103 km² (12% of the soil area). They occur under temperate, oceanic, boreal and arctic climates with the largest concentration of peatlands (97%) occurring in the Boreal and Subarctic Regions. These peatlands began to develop between 5500 and 9400 yr BP with an annual carbon accumulation of approximately 6.4 x 10⁶ to 9.8 x 10⁶ tC/yr. Canadian peatlands contain approximately 147.11 Gt of organic carbon with about 30% (44.18 Gt) of this carbon occurring in perennially frozen peatlands. Climate change predictions suggest that average annual air temperatures in northern Canada will increase by 3-5o C before the end of this century. A model for peatland sensitivity to climate change suggests that a large part of these peatlands, especially those that are perennially frozen, will be severely to extremely severely affected by climate warming. Peatlands were affected by climate change in the past, but these changes occurred at a slower rate than is predicted for the near future. This accelerated warming could have a severe impact on these peatlands with the southern peatlands being affected by drying and, consequently, by wildfires, the perennially frozen peatlands by severe thermal degradation and the coastal peatlands by flooding. Canadian peatlands play an important role in the global carbon balance. They store and sequester large amounts of carbon under the present climate but, under a warmer climate these peatlands could become a carbon source and could trigger very strong feedback mechanisms that would further increase climate warming.

Wetlands have been identified as significant sources of greenhouse gases. This study assessed the extent of methane (CH₄) suppression upon addition of iron or aluminum based coagulants to wetland soils. Metal based coagulants are used in the water industry to remove constituents of concern from solution, such as dissolved organic carbon (DOC). Currently, the addition of coagulants to degraded wetland environments to improve water quality and restore soils is under investigation. We also examined ¹³C signature shifts of CO₂ and CH₄ to assess changes in the pathways of methane production. Filtered water collected from an agricultural drain in the Sacramento-San Joaquin Delta, California, USA was treated with ferric chloride, ferric sulfate, and polyaluminum chloride. The resulting DOC-metal complex was then added to soil collected from the same area and incubated anoxically for 120 days. All three coagulants suppressed CH₄ and CO₂ emissions compared to the control. The ¹³C signature of the CO₂ remained relatively stable for all treatments (-18‰ to -21‰). Initial CH₄ from all treatments were enriched in ¹³C compared to the control (-62‰ to -67‰ compared to -77‰, respectively). The shifts in treatment CH₄ signature are similar to experiments where CH₃F is added to inhibit acetoclastic methanogenesis. Results imply addition of metal coagulants may repress CH₄ production in addition to sequestering C and improve water quality. Additional studies are required under field conditions to validate the results and to determine long-term impacts of adding metal coagulants to wetland soils.

LIGNIN DECOMPOSITION UNDER ALTERNATING REDOX CONDITIONS

Cerli Chiara^{*[1]}, Liu Qin^[2], Hanke Alexander^[1], Kaiser Klaus^[3], Kalbitz Karsten^[1]

^[1]University of Amsterdam ~ IBED - ESS ~ Amsterdam ~ Netherlands ^[2]Chinese Academy of Sciences ~ Institute of Soil Science ~ Nanjing ~ China ^[3]Martin Luther University Halle-Wittenberg ~ Soil Sciences ~ Halle (Saale) ~ Germany

In wet soils, lignin constitutes a major portion of the total organic matter (OM) because of hampered degradation under anoxic conditions. Paddy soils management involves alternating redox cycles with periodic changes in soil solution chemistry and microbial metabolism. Such an environment might promote either degradation or preservation of lignin, affecting the overall composition and reactivity of total and dissolved OM. We sampled two paddy soils used for submerged rice growing since 700 and 2000 years and two corresponding non-paddy soils. We incubated suspended material of the A horizons, under oxic and anoxic conditions, for 3 months, reversing the redox conditions for three weeks during the incubation. At day 2, 21, 42, 63, and 84 we analysed the suspension for lignin-derived phenols (by CuO oxidation) and phospholipids fatty acids. We aimed to determine effects of alternating redox conditions on lignin decomposition and microbial community. In paddy soils the relative short changes in redox conditions caused a decrease in the total microbial biomass but did not affect its composition. Under any redox condition, the abundance of fungi was low, explaining the lack of lignin breakdown or side chain oxidation during the entire incubation period. However, we found decreasing amounts of phenols during the incubation, especially after reversing redox conditions. The trend was same for paddy and non-paddy soils. Redox conditions appear to affect the extractability but not composition or degradation state of lignin, likely by inducing dissolution of mineral phases and/or changing their surface properties.

VARIATION OF SOIL MICROBIAL COMMUNITY STRUCTURE AND RHIZODEPOSIT CARBON ASSIMILATION IN PADDY FIELDS

Balasooriya Wajira K.^[1], Rajapakse R.m.c.p.^[2], Boeckx Pascal^{*[1]}

^[1]Ghent University ~ Department of Applied analytical and Physical Chemistry ~ Gent ~ Belgium ^[2]University of Peradeniya ~ Department of Soil Science ~ Peradeniya ~ Sri Lanka

*Paddy fields undergo fluctuations between flooded and drained soil conditions regulating the availability of soil oxygen and affecting the aerobic and anaerobic processes, including nitrification, methanogenesis and methane oxidation. These processes are mostly driven by microbial activity. In this study, in situ phospholipid fatty acids based stable isotope probing (PLFA-SIP) using $^{13}\text{CO}_2$ was used in a tropical lowland paddy field in Sri Lanka to assess the effect of variety and fertilizer type on microbial community structure and activity. Soil microbial community structure significantly varied between BG (an improved variety) and KH (a traditional variety) with either mineral or organic fertilizers. The high relative abundance of 16:1 ω 7c and 18:1 ω 7c, and lack of 18:1 ω 8c suggest that the methanotrophic bacteria *Methylosinus sporium* (Bodelier et al., 2009) is present associated especially with BG grown with organic fertilizers. In addition, the temporal variation of soil microbial community at vegetative, flowering and mature growth stages of BG covering both flooded and drained soil conditions was investigated. Approximately 4-5 cm of standing water level was maintained during the early crop growth until drainage of soil just after the end phase of flowering. A significant temporal variation of in situ soil microbial community structure and activity at different growth stages was evident. Reference: Bodelier, P.L.E., M.B. Grillisen, K. Hordijk, J.S.S.D. Damste, W.I.C. Rijpstra, J.A.J. Geenevasen, P.F. Dunfield. 2009. A reanalysis of phospholipid fatty acids as ecological biomarkers for methanotrophic bacteria. NITROGEN IMMOBILIZATION IN PADDY SOILS AS AFFECTED BY REDOX CONDITIONS AND RICE STRAW INCORPORATION

Said-Pullicino Daniel^[3], Birk Jago^[2], Cucu Maria Alexandra^[3], Sodano Marcella^[3], Glaser Bruno^[2], Celi Luisella^[3]

^[1]University of Turin ~ DiVaPRA - Agricultural Chemistry and Pedology ~ Turin ~ Italy ^[2]Martin Luther Universität Halle-Wittenberg ~ Institute of Soil Science, Biogeochemistry ~ Halle (Saale) ~ Germany ^[3]University of Turin ~ Soil Biogeochemistry Team, Rice Agroecosystem & Environmental Research Group ~ Grugliasco ~ Italy

N immobilization may represent one of the most critical aspects affecting long-term soil fertility and fertilizer efficiency. Redox processes play an important role in N availability and cycling in rice agro-ecosystems. Detailed information on the driving processes and factors controlling N immobilization in paddy soils is however, highly necessitated. This work aims at providing knowledge on the changes in fertilizer-N immobilization as a function of soil redox conditions and rice straw incorporation. A paddy soil collected from an ongoing long-term crop residue management trial (Vercelli, NW Italy) was treated with enriched ammonium-15N and incubated for five months under flooded or non-flooded conditions, with or without the addition of rice straw. Distribution of immobilized N among SOM fractions was assessed by combining aggregate-size and density fractionation, while microbial utilization of applied N was evaluated by compound-specific d15N analysis of amino sugars, important constituents of microbial cell walls. Fast immobilization of applied N (c. 37% applied N) was observed in both anoxic and oxic soils, however in the latter most of this N was released during incubation. The finer soil fractions in both macro- and microaggregates served as the greatest sink of immobilized N, sequestering 60-85% of the total immobilized N. Straw addition enhanced immobilization, particularly under anoxic conditions, with 12% of total immobilized N associated with the light fraction. The increasing incorporation of 15N into amino sugars also suggested that incorporation of straw to paddy soils may lead to the effective microbial-mediated immobilization and stabilization of significant portions of N inputs.

Many paddy soils are regularly burnt, thus leaving behind black carbon (BC) as the residue of incomplete combustion processes. This study aimed at elucidating the amount and rate at which BC contributes to the stable soil organic matter (SOM) pool after prolonged paddy management. For this purpose, soil depth profiles were sampled along a chronosequence of 0–2000 years of rice-upland crop rotation and adjacent upland systems (50–700 years) in the Bay of Hangzhou, Zhejiang province, China. The BC and its degree of condensation were assessed using benzene-polycarboxylic acids (BPCA) as geochemical markers. The results showed that despite regular burning SOM comprised only 8-10% of BC. Absolute BC contents were 60% higher in paddy than in non-paddy topsoils; the BPCA pattern resembled that of burnt straw on the fields. Between 2 and 60% of subsoil BC was stored in buried A horizons of the P700, P1000, and P2000 year old paddy fields. Throughout the chronosequence, SOC stocks increased until 300 years of paddy cultivation while BC stocks reached a maximum of 14 t ha⁻¹ after 700 years. In non-paddies, BC stocks were highest after 100 years of cropping and did not increase thereafter (9 t ha⁻¹). Hence, there is a slow and sustainable sequestration of C in charred forms upon prolonged management, but the contribution of BC to total C is smaller than found for other ecosystems of the world.

The paper presents the scale depending structures and processes in terraced paddy fields in southeast China. It focuses on the regularities of the spatial distribution of soil chemical and physical properties and on soil structural processes related to vertical and lateral water losses and solute leaching. The analysis of selected physical and chemical soil parameters on the catenary and catchment scale confirmed that even in old terraced landscapes, the original structures of catenary soil property distributions persist. The application of digital soil mapping techniques such as regression kriging and artificial neural networks revealed that the incorporation of topographical attributes is suited to characterize soil property distribution on both scales. Field scale investigations showed that paddy soils exhibit a dynamic soil water system which is driven by the mechanical seed bed preparation and the drying and wetting cycles, including flooded periods. It was found that the hydraulic properties mainly depend on the duration of cultivation as a rice paddy. Pedon and aggregate scale investigations demonstrated the dual porosity nature of paddy soils with a macropore network consisting of cracks and biopores penetrating the plough pan and the bunds. The shrinkage potential of the puddle layer was higher in older paddy fields than in younger ones while it was the opposite in the plough pan. In addition to newly proposed management strategies with recurrent wetting and drying cycles, we suggest maintaining (saturated) equilibrium conditions over longer periods to reduce the risks of water losses and chemical leaching involved with preferential flow.

In the Zhejiang province (P.R. China), during the past 2000 years new farmland was created through consecutive land reclamation. The soils were partly used for paddy rice, or, adjacently, for a variety of non-irrigated crops. This unique chronosequence allowed quantifying rates of paddy soil formation in direct comparison with soils under non-paddy management. Our present data indicate that three fundamental phases of paddy soil development can be delineated from essential soil chronosequence properties: During the first phase after land embankment (several decades), soil formation was driven by short-term biogeochemical processes like desalinisation, formation of paddy-specific microbial communities, and the development of a dense plough pan, which partly decoupled soil development in topsoil from subsoil processes. During the next two centuries (intermediate phase), development processes are related to the dissolution of carbonates. Frequent flooding and drainage accelerated this process compared to soil development under non-paddy agricultural management. Soil organic matter contents still rise in the topsoils. Within the paddy soil profile, we identified two time domains above and below the plough pan: while processes in topsoils are accelerated due to management, decalcification and related processes are considerably slower in the subsoils. After decalcification of the entire soil profile, long-term processes start, which are partly related to mineral transformations (final phase). Mn and Fe oxides, which are reduced in the topsoil, pass the plough pan in the long run and accumulate in the subsoil, where they crystallise in the interiors of the aggregates. Concurrently, accumulation of organic matter reaches saturation in topsoils.

PROTECTIVE EFFECT OF SOIL SEALING - HEAVY METALS AND POLYCYCLIC AROMATIC HYDROCARBONS CONTENT IN EKRANIC TECHNOSOLS

Charzynski Przemyslaw*^[1], Michal Dabrowski^[2]

^[1]Nicolaus Copernicus University ~ Department of Landscape Geography ~ Torun ~ Poland ^[2]Nicolaus Copernicus University ~ Department of Soil Science ~ Torun ~ Poland

Sealing is one of the major problems of soil degradation. It is a phenomenon occurring in all urban areas as well, though on a smaller scale, in rural areas, especially in Western world. Aim of the study was to evaluate protective effect of soil sealing on Ekranic Technosols. There were selected 2 study sites in Torun, Poland located in close proximity of a busy thoroughfares. In both study sites 3 soil profiles were made – under asphalt sidewalk, under concrete paving slabs and reference one, on the lawn. All was situated at a distance of 5-10 meters from the road. In the samples taken from topsoil the content of lead, copper, zinc and cadmium was determined using Atomic Absorption Spectrophotometry (AAS) after mineralization in a mixture of HF + HClO₄. The analysis of 17 polycyclic aromatic hydrocarbons was performed by gas chromatography/mass spectrometry (GC/MS) after extraction with dichloromethane. Results show that sealed soils contain much smaller amounts of Pb, Cu, Zn, Cd and PAHs in comparison with reference ones. The content of most dangerous PAH - benzo(a)pyrene was 4 times smaller under concrete paving and more than 10 times lower under the asphalt surface than in unsealed soil. Similar trend can be observed in the case of other PAHs and analyzed heavy metals. It seems that the sealing, in addition to the negative effects, may bring also some benefits isolating the soil from contaminants. The research was financed by the Polish Ministry of Science and Higher Education (project N N306 4637380).

TRAFFIC SOILS OF SAINT-PETERSBURG

Abakumov Evgeny*^[1], Tomashunas Vitaliy^[1]

^[1] Saint-Petersburg State University ~ Soil science and soil ecology ~ Saint-Petersburg ~ Russian Federation

Traffic areas is very important part of big cities, they occupies a huge areas and affect on soil and ground cover very intensively. The history of soil formation and construction discussed in details for ring road in southern part on Saint-Petersburg city. Soil history here has 4 stages. The first was a change of typical sod-gleyic soil by ground drainage during the railway constructions. Later, soils were covered by building garbage for 20-40 years. Material of waste shows the evident features of soils formation: humus accumulation, losses of carbonates, formation of fine earth due to weathering and structure formation. Finally, in the beginning of XXI century these soils were partially destroyed, construction of road affects the surface relief and reclamation of soil by fertilized grounds, imported from Leningrad region. On the last, modern stage, these constructed soils, show an evident features of surface erosion and fine earth consolidation. Chemical and physical properties of soils, as well as its morphological characteristics are discussed in report.

DIFFERENCES IN CARBON AND NITROGEN STOCKS AND ISOTOPIC COMPOSITIONS REGARDING THE EXPOSURE TIME OF SOILS TO URBAN CONDITIONS: THE CASE OF STREET TREE-PIT SOILS FROM THE CITY OF PARIS

Rankovic Aleksandar^[1], Izac Benjamin^[2], Lata Jean-Christophe^[1], Leloup Julie^[1], Zanella Augusto^[3], Barot Sébastien^[4], Abbadie Luc^[1]

^[1]Université Pierre et Marie Curie - Paris VI ~ UMR (CNRS) 7618 Bioemco ~ Paris ~ France ^[2]Université Paris-Sud ~ UMR (CNRS) 7618 Bioemco ~ Orsay ~ France ^[3]Università degli Studi di Padova ~ TeSAF ~ Padova ~ Italy ^[4]Institut de Recherche pour le Développement ~ UMR (CNRS) 7618 Bioemco ~ Paris ~ France

*When "new" soils, mostly deprived of technogenic materials, are imported into urban from peri-urban areas, an important question is to understand how these soils will evolve when exposed to urban environmental conditions. The soils of street tree-pits in Paris could be an interesting subject for such investigations. Indeed, when the city of Paris plants a new tree, it removes all the previous soil from the pit and replaces it by a newly imported soil from peri-urban agricultural areas. Since there are no artificial nutrient inputs during the tree's life, whilst its fallen leaves are removed from the soil, it can be expected that soil carbon and nitrogen stocks would decrease with time. Furthermore, due to specific urban isotopic signatures of atmospheric carbone and nitrogen (strongly negative $\delta^{13}\text{C}$, strongly positive $\delta^{15}\text{N}$), we can respectively expect a decrease and an increase of soil $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ with the aging of trees. The presentation will show the results of a campaign realized in the summer of 2011 in Paris, where the soils (at 10-30 cm and 30-40 cm depths) and leaves (4 on the lower canopy) of 79 silver lindens (*Tilia tomentosa*) were sampled. The sites were chosen according to three dbh (diameter at breast height) classes : 7-15 cm ($n = 28$) ; 32-43 cm ($n = 29$) ; 56-73 cm ($n=22$). The results will be discussed regarding our hypotheses and other upcoming analyses on soil microbial communities and their activities.*

TECHNOLOGICAL MATERIALS IN (URBAN) SOILS: A NEW WAY OF IDENTIFICATION USING FT-MIR SPECTROSCOPY

Stumpe Britta^{*[1]}, Michaelis Xandra^[1], Engel Thomas^[1], Marschner Bernd^[1]

^[1]Geographical Institute/ Ruhr-University Bochum ~ Soil Science & Soil Ecology ~ Bochum ~ Germany

Technological substrates like slags or ashes are an elementary part of (urban) soils. The identification of these substrates in the field is often very difficult since they may have a similar appearance (grain size, colour) like natural soil substrates. Since technological substrates can be highly contaminated with heavy metals and affect the soil functions – such as water storage capacity or filter function – a reliable identification of slags and ashes is important. We determined spectra of 180 different soils and over 100 spectra of technological materials via FT-MIR spectroscopy. Within one group of substrates, e.g. blast furnace slag, the spectra were very similar, whereas clear differences were found between different groups of technological materials (for example between blast furnace slag and different slags from metallurgical processes) and also clear differences to the spectra of the soils. The spectra of the technological substrates were subjected to statistical analysis using the SIMCA (Soft Independent Modeling of Class Analogy) method which now allows us to identify an unknown slag material exactly. In a next step we mixed different technological substrates with twelve selected soil samples in various concentrations and determined the spectra of these mixtures. The difference between the soil samples and the soil samples with technological additions were smaller than in the first experiment so that we had to transform the data into a new form for further statistical analysis. This procedure provides an opportunity for the rapid characterisation of soils regarding their content of technological substrates.

TOOLS FOR RATIONAL PLANNING AND URBAN SOIL MANAGEMENT

Vrscaj Borut^[1], Vernik Tomaž^[1], Sinkovec Marjan^[1], Bergant Janez^[1]

^[1]A ~ Centre for Soil and Environment Research ~ Ljubljana ~ Slovenia

Proportionate soil information is of major importance for rational urban planning and more sustainable urban development. In general we are facing a lack of soil information for urban/suburban areas. However, when available these are difficult to efficiently interpret and use by non-soil experts -mainly planners and city administrations. Focused soil information such as soil quality, contamination, soil suitability..., should that for be available within effective and end-user oriented web-based system equipped with evaluation and risk assessment tools. EU-Central UrbanSMS project joined the partners from Stuttgart, Vienna, Prague, Bratislava, Pulawy, Milano, Torino and Celje. Main project goals were to set strategies and to develop tools for lowering soil consumption and improving planning and soil management decisions. The soil information should be structured and spatial soil evaluation tools developed for non-expert use. A special attention should be paid to the flexibility of tools in order to meet different data quality, availability and threshold values. The presentation gives an overview of the web GIS portal with predefined planning and soil management tools. The system is used for visualization, analysis, and interpretation of soil and related data. The tool results steer planers towards lowering soil consumption of high quality soils and more sustainable planning decisions. Several tools will be presented: Loss of Soil Resource to assist the planning decisions and to protect best quality soils; Ecosystem Soil Quality to assess the environmental importance of soils; Water Drainage to estimate the potential water logging and Agricultural Soil Quality to preserve best agricultural land.

INFLUENCE OF SOIL AERATION ON ROOTING AND GROWTH OF THE BEUYS-TREES IN KASSEL, GERMANY

Weltecke Katharina*^[1], Gaertig Thorsten^[1]

^[1]HAWK-HHG ~ Fakultät Ressourcenmanagement ~ Göttingen ~ Germany

Soil aeration is one important factor for tree growth. Oxygen must be taken from the atmosphere for root respiration, and carbon dioxide must be discharged reversely. At urban sites several soil cover types with different aeration conditions alternate on a small scale, competing with the natural function of soil as living space for roots. During documenta 7 in 1982, the artist Joseph Beuys initiated the spectacular landscape art project "7.000 Oaks". 7.000 nearly even-aged trees were planted across the city of Kassel, Germany, offering ideal conditions to investigate the influence of specific site factors on root and tree growth. At 8 different sites featuring 36 Beuys-oaks and 15 Beuys-planes, top soil gas diffusivity, soil CO₂ concentration and soil respiration of different soil cover types were measured and correlated with root and tree growth. Soil gas diffusivity as well as soil respiration depended on the degree of sealing. The lowest gas diffusivities and respiration rates were found at sealed sites and the highest values were measured at vegetated sites. Soil respiration was primarily controlled by soil gas diffusivity. Soil CO₂ concentration was not strictly linked to the coverage type. Rooting and growth of oaks were decisively shaped by the gas diffusivity of the soil cover. Rooting, height and diameter of oaks decreased significantly with decreasing gas diffusion coefficients. In contrary, this correlation was not detectable for planes. Vitality of urban trees can be controlled by the design of the tree site and the choice of the species.

Soil erosion and weathering rates can vary significantly in both time and space. Therefore the interaction between erosion and weathering has a complex spatio-temporal effect on soil properties. However, so far, our ability to quantitatively describe the erosion-weathering dynamics has been extremely limited. Our mARM3D soil-landscape model explicitly calculates three-dimensional soil evolution as a function of surface erosion and profile weathering. Here we discuss simulations of the affect of long-term (Quaternary) climate fluctuations on the spatial distribution of evolving soils. A simple assumption is made about the impact of climate on weathering and erosion rates. Hillslope and catchment-scale soil evolution were simulated over a 400,000 year period using the Vostok (Antarctica) ice-core data as a climatic input. The results consistently show that: (1) The effect of climatic forcing on soil evolution varies in space to the point where different parts of a hillslope have opposite trends in grading distribution with cooling/warming. (2) Soil evolution continues long after a sharp climatic change so there is a lag in adjustment to the changing climate. (3) The timescale of the soil adjustment lag to changing climate changes varies in space. These findings have significant implications to our understanding of the pedogenic system and demonstrate the attractiveness of using mARM3D as a virtual-laboratory, that is a tool for desktop studies of erosion and weathering dynamics.

S02.01 -2

**ALTERATION OF SOIL ORGANIC MATTER DURING INITIAL MARSH SOIL DEVELOPMENT
AT THE SOUTHERN NORTH SEA COAST**

Giani Luise^{*[1]}, Marie Spohn^[2]

^[1]University of Oldenburg ~ Department of Soil Science ~ Oldenburg ~ Germany ^[2]University of Goettingen ~ Dept. of Soil of Temperate Ecosystems ~ Göttingen ~ Germany

Marshes constitute a transition between marine and terrestrial ecosystems in which soils develop from marine sediments. The question we address in this paper is how organic matter (OM) and the relationship between mineral skeleton and OM are altered during initial soil development in saltmarshes. For this purpose young soils in the lower, higher and upper zone of saltmarshes at six sites on the southern North Sea coast were studied. It was found that organic carbon (OC) and nitrogen (N) contents increased significantly with increasing age of the soils. The $\delta^{13}\text{C}$ signature of the OC strongly decreased from lower to upper marsh indicating a decrease in the proportion of marine-derived OC. The decrease of sea-derived OC was associated with an increase in the C/N ratio, which can be attributed to the difference in C/N ratio between sea- and land-derived OM inputs. Increases in OC and N contents during soil development were due to increases in the coarse size fraction ($>200\ \mu\text{m}$) and went along with increases in the content of hot water extractable C and N (Chwe and Nhwe). Clay contents and hence the proportion of OM found in the fraction ($<2\ \mu\text{m}$) decreased with soil development due to sedimentation dynamics. The ^{13}C signature of the OC stored in this fraction was higher as the signature of the bulk OC, indicating that in this fraction OM is relatively stable and is mainly of terrestrial origin sorbed to the clay minerals before they were transferred into the sea.

S02.01 -3

MECHANISMS OF ORGANIC MATTER ACCUMULATION ON GLACIER FOREFIELDS AND INLAND SAND DUNES DURING INITIAL SOIL FORMATION

Dümig Alexander^[1], Kögel-Knabner Ingrid^[1]

^[1]Technische Universität München ~ Lehrstuhl für Bodenkunde ~ Freising-Weihenstephan ~ Germany

We used chronosequences after glacier retreat and on sand dunes to identify processes of organic matter (OM) accumulation during initial soil development. The OM chemistry was assessed by ¹³C NMR spectroscopy and acid hydrolysis. Mineral phases were characterized by X-ray diffraction, N₂ adsorption, oxalate and dithionite extraction. In the glacier forefield, we found rapid OM accumulations in bulk soils within 100 yrs of soil formation. Similarly, the amount of poorly crystalline Fe and Al phases increased reflecting the growing potential for OM stabilization. Clay fractions showed strongly increasing OC loadings with age resulting in decreasing specific surface area (SSA) of minerals. The SSA of H₂O₂-treated clays was strongly related to oxalate soluble Fe which was strongly correlated with OC. Clay-bound OC of 15-year-old soils was of refractory nature owing to high proportions of carboxyl and aromatic C may due to inherited OM. With increasing age, these functional groups decreased associated with increasing contents of microbial-derived carbohydrates and proteins. Accumulation of alkyl C was detected in older soils. The colonization of biological soil crusts resulted in higher concentrations of OC and Fe oxides compared to parent materials. Vegetation succession was combined with specific signatures of microbial-derived carbohydrates which were the major OC input to the soils. Initial soil formation and SOM accumulation is fast. The accumulation of SOM is linked with weathering and formation of Fe oxides leading to specific accumulations of carbohydrate-C. The sequential accumulation of different organic compounds indicates layering of OM during the evolution of organo-mineral associations.

**EVOLUTION AND TRANSFORMATION OF MINERAL MATERIALS OF COAL-MINE SPOIL
HEAPS: INDICATORS OF PEDOGENESIS**

Gauthier Arnaud^{*[1]}, Michel Dubois^[1], Mathieu Thevenot^[1]

^[1]Laboratoire de Génie-Civil et géo-Environnement ~ Université Lille1 ~ Villeneuve d'Ascq ~ France

As a result of coal mining activity, many waste disposal sites were created in the Nord-Pas-de-Calais landscape during the two last centuries. More than three hundred spoil heaps have been referenced in this region. Natural and anthropogenic processes considerably affect their evolution, such as natural combustion, weathering and colonisation by plants. Revegetalisation can be due either to natural processes or to reconversion for touristic use or landscaping. The aim of this work is to constraint the successive steps of soil development on spoil heap surface, in order to understand their evolution for the next decades. The first step of natural soil formation is mineral transformation during weathering. Initial rock fragments, mostly black shales, were investigated using Raman microspectroscopy and compared to the altered fraction. Concomitant with the disaggregation, neoformation and dissolution/precipitation processes lead to the appearance of new minerals, such as clay fractions and amorphous phases. Thus, an evolution of the mineralogy, but also of the texture and structure of the spoil heaps was observed. In the case of anthropogenic reconversion of the spoil heaps, evolution is largely affected by adjustment policy that modify the kinetic and intensity of alteration processes. Different tests have to be done as a function on the nature of vegetation used during reconversion.

VISUALIZATION OF SOIL STRUCTURE MODIFICATIONS AND INFILTRATION PATTERNS BY GROUND-DWELLING BEETLE LARVAE AND MOSS VEGETATION

Badorreck Annika*^[1], Gerke Horst H.^[2]

^[1]Brandenburg University of Technology ~ Research Centre Landscape Development and Mining Landscapes (FZLB) ~ Cottbus ~ Germany ^[2]Leibniz-Centre for Agricultural Landscape Research (ZALF) ~ Institute of Soil Landscape Research ~ Müncheberg ~ Germany

An artificial catchment was constructed to study initial soil and ecosystem development. As a key process, the pore structure dynamics in the soil at the surface strongly influences erosion, infiltration, matter dynamics, and vegetation establishment. This presentation focuses on observations of soil structure modifications from ground beetles and moss vegetation and its effect on water flow at the surface. The surface soil with beetle burrows was sampled in plastic rings in two replicates along a vegetation gradient from dense moss cover to bare soil, and was scanned with micro-X-ray computed tomography. Infiltration dynamics were visualized with neutron radiography on two slab-type soil samples in 2D. The burrowing activity leads to mostly vertical channels with a locally compacted wall. Also isolated vesicular macro pores were found in the bottom part of the moss covered sample, more evenly distributed in the sparsely vegetated sample. A dense moss cover seems to stabilize the first centimeter of the soil. Also layer of erosion sediment was only visible in samples from non-vegetated patches. The neutron radiograph series showed preferential flow. Water drop penetration time tests on air dry subsoil revealed water repellency, what probably contributes to the observed bypass flow. A water repellent bottom part of the soil acted as internal barrier for water movement and water entered the burrow from the sides after a moisture saturation threshold was exceeded. The observations demonstrate relatively high abiotic and biotic dynamics of soil pore structure in the soil surface even during the very early development stages.

TRANSFORMATION OF ¹³C-LABELLED LITTER IN SANDY, INITIAL SOILS

Zimmermann Claudia*^[1], Wolfgang Schaaf^[1]

^[1]BTU Cottbus ~ Soil Protection and Recultivation ~ Cottbus ~ Germany

Soils from the artificial catchment Chicken Creek were studied in microcosm experiments. 50 soil columns were filled with two textural variations of the catchment soils (pure sand and loamy sand) and ¹³C-labelled litter of two plant species (*Calamagrostis epigejos* and *Lotus corniculatus*) was added. The soil columns were placed in a climatic chamber with controlled temperature, gas and water fluxes. CO₂, DOC and nitrogen fluxes were measured over 80 weeks. CO₂ and DOC were analyzed for isotopic composition. Litter addition increased the decalcification of the soil substrates. Lotus litter decomposed faster due to the lower C/N ratio. Nitrification and leaching of dissolved nitrogen was only found for the Lotus treatments. DOC leaching was higher for the loamy sand compared to the pure sand columns. The highest leaching of litter-derived DOC was found for the pure sand and leaching of soil-derived DOC only for the loamy sand treatments.

**SOIL MICROBIAL COMMUNITY DEVELOPMENT AND PLANT-MICROBE INTERACTIONS
ALONG A GLACIAL CHRONOSEQUENCE**

Hahn Aria^{*[1]}, Quideau Sylvie^[1]

^[1]University of Alberta ~ Renewable Resources ~ Edmonton ~ Canada

*Despite previous research into primary succession in terms of vegetation development, soil formation and microbial functional diversity, the processes by which newly exposed ecosystems undergo succession are still relatively poorly understood. We aimed to measure soil microbial community composition and functional diversity, as well as determine the influence of Engelmann spruce (*Picea engelmannii* Parry) and yellow mountain avens (*Dryas drummondii* Rich.) on soil microbial community succession along a Canadian glacier chronosequence. Soil microbial composition and functional diversity were assessed using phospholipid fatty acid (PLFA) analysis, substrate induced respiration and enzyme activity analysis. To the best of our knowledge, this is the first study to include peroxidase and phenol oxidase activities of soil microbial communities along any glacial chronosequence. Increased microbial biomass, enzyme activity and substrate respiration along the chronosequence, as well as significant correlations between the microbial respiration of N-acetyl-glucosamine, protocatechuic acid, glucose and percent soil N indicated that the soil microbial community was responding to changes in the soil environment. Plant-microbe interactions changed after 40 since deglaciation, as yellow mountain avens had a measurable effect on microbial biomass only in the mid-successional stage. Low β -glucosidase activity rates and glucose respiration rates in the early successional stage soils, along with a significant correlation between these two measures, indicated that the early successional stage soil microbial communities were not readily able to utilize glucose. Thus, alternative or multiple substrates should be used in place of glucose when soil microbial analyses are being performed on early successional stage soils.*

Microbial food webs are basis for functional and stable ecosystems. However, the development of microbial food webs and their role in "young" ecosystems is unclear. Due to a continuous glacier retreat since the middle of the 19th century, glacier forefields have expanded offering an excellent opportunity to study food web dynamics different developmental stages. In this study, litter degradation and the corresponding C fluxes into microbial communities were investigated along the forefield of the Damma glacier (Switzerland). ¹³C enriched litter of the pioneering plant *Leucanthemopsis alpina* (L.) Heywood was incorporated into the soils that have been free from ice for approximately 10, 60, 100 and more than 700 years. The structure and function of microbial communities were identified by ¹³C analysis of phospholipid fatty acids (PLFA) and phospholipid ether lipids (PLEL). Results showed increasing microbial diversity and biomass, and enhanced proliferation of bacterial groups as ecosystem development progressed. Initially, litter decomposition proceeded faster at the more developed sites, but at the end of the experiment loss of litter mass was similar at all sites, once the more easily-degradable litter fraction was processed. Incorporation of ¹³C into microbial biomass was evident during the first weeks of litter. ¹³C enrichments of both PLEL and PLFA biomarkers following litter incorporation occurred at all sites, suggesting similar microbial foodwebs at all stages of development. Nonetheless, the contribution of bacteria, especially actinomycetes to litter turnover became more pronounced as soil age increased in detriment of archaea, fungi and protozoa, more prominent in recently deglaciated terrain.

Most of the glaciers in the Alps are currently retreating due to climate change. The newly formed soil is composed of granitic sand and rocks, where harsh conditions with large temperature and soil moisture shifts prevail. This makes these environments ideal for studying microbial adaptation. It is known that altering microclimatic conditions influence microbial biomass and activity. The aim of the present study was to investigate the extent of these changes in relation to microclimatic shifts. To achieve this, we chose three sites for transplantation of granite sand with a defined soil age (approx. 10 years) in front of the Damma glacier in Switzerland. The sites differed in the amount of sunlight hours they receive due to the shading of the nearby mountains. At these three sites, 15 pots per site were filled with local granitic sand and five transplanted to each of the other two sites, five pots remained at the original site. During the vegetation period, we continuously monitored soil temperature and moisture. The dynamics of the bacterial and fungal community structure was analyzed with T-RFLP analyses. Activities of enzymes involved in the breakdown of glucose, proteins and chitin were also determined. The activity of bacteria and fungi were determined using the leucine incorporation and acetate-in-ergosterol incorporation methods. Our results suggest that the communities react to the transplantation of soil along a temperature gradient, but to a lesser extent than expected. Furthermore it seems that the seasonal influence is more significant for the microbial communities than the transplantation.

ORGANIC MATTER ACCUMULATION AND MICRO-AGGREGATE FORMATION IN SOIL CHRONOSEQUENCES IN AUSTRIA, ICELAND AND SWITZERLAND

Lair Georg J.*^[1], Lehtinen Taru^[4], Gísladóttir Gudrun^[2], Bernasconi Stefano^[3], Blum Winfried E.h.^[1]

^[1]University of Natural Resources and Life Sciences (BOKU) ~ Institute of Soil Research ~ Vienna ~ Austria ^[2]University of Iceland ~ Faculty of Life and Environmental Sciences ~ Reykjavik ~ Iceland ^[3]ETH Zürich ~ Geological Institute ~ Zürich ~ Switzerland ^[4]University of Natural Resources and Life Sciences (BOKU)/University of Iceland ~ Institute of Soil Research ~ Vienna ~ Austria

Soil organic matter (SOM) is a main driver for the build-up of soil structure and is therefore governing the main physical and chemical processes of soil development. However, SOM dynamics in the initial stages of soil development as well as the stability of SOM within micro-aggregates (<250 μm) and/or by sorption on soil mineral surfaces are still poorly understood. Even less is known about the impact of different plant covers on these short to medium-term processes. In the present study we assess SOM quantity and its chemical composition within micro-aggregates of genetic soil horizons, developed under forest and natural grassland. The studied soils comprise an age gradient of approximately 5000 years in the former floodplain area of the Marchfeld (Austria) and hundreds of years in glacial forefields at the Skaftafellsjökull Glacier (Iceland) and at the Damma Glacier (Switzerland). This allows for investigating the influence of SOM on soil micro-structure build-up on different parent material and under different climates. Results of our study show that ecosystems progressively evolve through the biogeochemical processes of SOM accumulation and soil structure formation.

S02.02 -5

BIOLOGICAL ACTIVITIES OF SOILS DEVELOPING ON A 50-YEAR-OLD COAL-WASTE HEAP OF THE MINING BASIN OF PROVENCE (SOUTH-EAST OF FRANCE)

Clouard Mélanie*^[1]

^[1]Aix-Marseille Université ~ CEREGE - IMEP ~ Aix en Provence ~ France

The coal mining industry in Provence (France) left scattered coal-waste heaps that are a mixture of various materials extracted from the mine (marno-calcareous shales, lignite). Some of these heaps have been left unattended for more than 50 years and early ecosystems have developed. Microbial processes are responsible for the turnover of organic matter, but little is known on microbial activity of these newly formed soils, as well as the impact of lignite on it, especially under Mediterranean climate. The study aims at 1) highlighting differences in microbial properties according to heap topography, lignite and organic matter enrichment; 2) comparing with natural soils developed under similar geomorphological and bioclimatic conditions. Soils were sampled on the South hillside at 355m NGF (top), 350m, 345m and 340m (bottom). Seven enzymatic activities involved in the main biogeochemical cycle of CNPS, are measured on 30 soil composite samples collected at 0-5 cm and 15-30 cm depth. Moreover respirometric measurements performed with OxitopTM system and catabolic profiles of microbial communities (measured by Biolog[®]) were performed. Additionally to biological measurements, physico-chemical properties and SOM quality characterisation by ¹³C SS CPMAS NMR were performed. The results show a gradient of the soil properties according to topography and presence of lignite. Increase in recalcitrant compounds (aromatic C) is shown in soils where lignite is present. Enzymatic activities also vary according to topography and lignite content, and are larger than in natural soils. Thus lignite seems to affect significantly biological functions involved in pedogenetic processes of such early ecosystems.

**SPATIAL CARBON AND NITROGEN DISTRIBUTION AND ORGANIC MATTER
CHARACTERISTICS OF BIOLOGICAL SOIL CRUSTS IN THE NEGEV DESERT (ISRAEL)
ALONG A RAINFALL GRADIENT**

Drahorad Sylvie^{*[2]}, Peter Felix-Henningsen^[2], Kai-Uwe Eckhardt^[3], Peter Leinweber^[3]

^[1]Justus Liebig University ~ Institute for Soil Science and Soil Conservation, Research Centre for Biosystems, Landuse and Nutrition (IFZ) ~ Giesen ~ Germany ^[2]Justus Liebig University ~ Institute for Soil Science and Soil Conservation, Research Centre for Biosystems, Landuse and Nutrition (IFZ) ~ Giessen ~ Germany ^[3]University of Rostock ~ Soil Science, Faculty of Agricultural and Environmental Sciences ~ Rostock ~ Germany

In the NW Negev the sand dunes are restabilized by biological soil crusts (BSC) since 1983. These BSC influence surface stability and are important contributors of organic matter. Because a multivariate examination of the spatial distribution of organic carbon (OC) and nitrogen (N) and a characterization of crust organic matter composition is missing, we examined BSC and topsoils at three depths and three contrasting relief positions along a rainfall gradient (90 mm a⁻¹ to 170 mm a⁻¹). To test the impact of soil moisture on BSC organic matter composition, selected samples were analysed by pyrolysis-field ionization mass spectrometry (Py-FIMS) to characterize differences in the molecular composition of organic matter in relation to depth and rainfall gradient. Topcrusts (0-2 mm) showed higher concentrations of OC and N and a relative enrichment in bacteria, as indicated by proportionally larger contents in N-acetylmuramic acid (m/z 167+276) than the subcrusts (2-40 mm). The subcrust had more thermally stable organic matter compounds and a relative enrichment in cyanobacteria, as indicated by proportionally larger contents of hexadecadienoic acid (m/z 252). With increasing rainfall the m/z signal intensities of pentoses and N-acetylmuramic acid increased, implying an enrichment of plant material and bacteria. We conclude that the spatial distribution of OC and N is characterized by factors such as depth, relief and rainfall that are closely linked to the amount of available moisture. Moreover Py-FIMS characterized the BSC organic matter composition and enabled us to identify main biomass contributors changing with BSC composition and stage of development.

A QUALI-QUANTITATIVE EVALUATION APPROACH TO PEDODIVERSITY BY MULTIVARIATE ANALYSIS. INTRODUCTION TO THE CONCEPT OF "PEDOCHARACTER".

Buondonno Andrea^{*[1]}, Odierna Pierclaudio^[1], Capra Gianfranco^[2], Coppola Elio^[1], Grilli Eleonora^[1], Vacca Sergio^[2]

^[1]Seconda Università degli Studi di Napoli ~ Dipartimento di Scienze Ambientali ~ Caserta ~ Italy ^[2]Università degli Studi di Sassari ~ Dipartimento di Scienze Botaniche, Ecologiche e Geologiche ~ Nuoro ~ Italy

A model has been developed for the interpretation of the complexity of pedological systems; this is referred to as "pedocharacter". The main aim of the model was to reduce the variables able to define soils and their relationships with the environment through the following quali-quantitative approach: i) definition of a fair number of qualitative characters; and ii) development of an analytic function, defined as "Land Relevance of the Factor". This enables a quantitative estimation of complexity aimed at analyzing, understanding and mapping pedological system variability. On this basis, an investigation was carried out on topsoil and subsoil characterizing the Sele River Plain (Campania, Italy), with the aim of assessing the differences between surface and sub-surface horizons by means of a comparative estimation prepared through the use of a "pedocharacter" index. In the study area, topsoil pedodiversity (range = -1.31 to 4.50) generally showed higher intensity than in the subsoil (-1.16 to 4.2). In these terms, the numbers and types of variables used for "pedocharacter" characterization were higher in the topsoil. Additionally, plant cover appeared equally important for the definition of topsoil (mainly herbaceous cover) and subsoil (mainly woodland cover) characters. The results obtained have led to the development of an integrated pedometric model for the quali-quantitative assessment of "pedocharacter" and, consequently, of pedodiversity. This result is important for basic and applied pedology, suggesting the need for a general refinement of qualitative diagnostic and taxonomic tools, with a view to defining quantitative aspects that are not strictly connected with pedogenic processes.

CHRONOSEQUENTIAL ALTERATIONS OF PROPERTIES OF POST-AGROGENIC STAGNIC ALBELUVISOLS IN THE TAIGA OF RUSSIA UNDER SELF-RESTORATION.

Kalinina Olga^[1], Sergey Goryachkin^[2], Dmitriy Lyuri^[2], Luise Giani^[1]

^[1]C.-v.-O. University of Oldenburg ~ Department of Soil Science ~ Oldenburg ~ Germany ^[2]Russian Academy of Sciences ~ Institute of Geography ~ Moscow ~ Russian Federation

This chronosequential study focuses on the vegetation succession, pedogenesis, soil nutrient dynamics, carbon stocks, and functionally different carbon pools of post-agrogenic Stagnic Albeluvisols under self-restoration in the taiga zone of the European part of Russia. The durations of agricultural abandonment were 4, 12, 17, and 68 years. During self-restoration, the vegetation developed towards spruce forest with grass and the soils towards natural Stagnic Albeluvisols. Pedogenesis resulted in the formation of moder cover layers, Ah horizons, and eluvial features within the Ap horizons. The chronosequence showed a decline of stocks of plant available phosphorus and potassium, pH decrease from 5.6 to 3.9, and a decrease of base saturation from 100 to 32% in the upper mineral topsoils. Soil organic carbon (SOC) content increased in the soil depth 0-8cm but decreased slightly in the soil depth 8-20cm. The carbon stocks increased from 2.2 to 4.4 kg C m⁻² in the upper 20cm because of the carbon sequestration within the mineral topsoil and cover layer. Carbon sink functioning is larger in self-restorated Stagnic Albeluvisol than in natural ones. The organic carbon of the clay fraction showed no quantitative alterations. Free particulate organic matter (POM) increased from 6.7 to 33.3% of SOC in the soil depth 0-2cm and from 5.6 to 12.1% of SOC in the soil depth 2-20cm. Occluded POM decreased by approximately 10% of SOC in the upper 20cm of mineral topsoil. The results of the study show no full self-restoration of Stagnic Albeluvisols within the investigated time-scale of 68 years.

CARTOGRAPHIC AND CLASSIFICATION MODELS FOR REPRESENTATION OF THE TERRITORY PEDODIVERSITY

Khitrov Nikolay^[1], Cheverdin Yuri^[2], Chizhikova Natalya^[3], Rogovneva Ludmila^[1]

^[1]V.V.Dokuchaev Soil Science Institute ~ Department of genesis and reclamation of saline and sodic soils ~ Moscow ~ Russian Federation ^[2]Voronezh Research Institute of Agriculture ~ Department of agricultural soil science ~ Talovaya ~ Russian Federation ^[3]V.V.Dokuchaev Soil Science Institute ~ Laboratory of soil mineralogy and micromorphology ~ Moscow ~ Russian Federation

To characterize and estimate pedodiversity at the territory of agroforestlandscape in Kamennaya Steppe (Talovaya district, Voronezh region, Russia) located in the centre of the East-European Plain the map of soil cover pattern was compiled (scale 1:25000). It shows 95 contours represented by 61 soil combinations with unique composition and environmental conditions that are characterized by detailed soil maps (scale 1:1000) and soil catena. Soil diversity is associated here with the following soil processes: humus accumulation, zoogenic mixing, migration and accumulation of soluble salts and carbonates, solonetz process, vertigenesis, redox processes due to the groundwater impact and/or seasonal surface water stagnation, erosion, soil transformation caused by plough and tillage. Three soil classification systems (soil classification of the USSR, 1977; soil classification of Russia, 2004, 2008; WRB, 2006) were used to estimate the pedodiversity at the studied territory. The soils are represented by 5 WRB reference soil groups (Chernozems, Phaeozems, Solonetz, Vertisols, Stagnosols) or 6 soil types according to the soil classification of the USSR (1977) or 15 soil types according to the soil classification of Russia. The latest soil classification of Russia (2004, 2008) reveals the greatest pedodiversity (127 taxonomic classes) at the given territory taking into consideration diagnostic criteria for anthropogenic transformation of soils. WRB (2006) allows estimating approximately the same pedodiversity (71 classes) as compared to that (77 classes) determined by the soil classification of the USSR (1977). The study was carried out at the support of Russian Foundation for Basic Research, projects no. 06-04-08323, 08-04-01195, 11-04-00710.

PEDODIVERSITY IN A TROPICAL HIGHLAND COUNTRY. THE CASE OF RWANDA.

Verdoodt Ann*^[1], Peter Finke^[2], Geert Baert^[3], Eric Van Ranst^[2]

^[1]Ghent University ~ Department of Soil Management ~ Gent ~ Belgium ^[2]Ghent University ~ Department of Geology and Soil Science ~ Gent ~ Belgium ^[3]University College Gent ~ Department of Plant Production ~ Gent ~ Belgium

Rwanda, even though being a small landlocked country, hosts a great diversity in climatic, geologic, and geomorphic conditions. This diversity is also reflected in its soil resources. A complex pattern of soil mapping units was deployed to characterise the Rwandan soilscape, which has been surveyed and mapped at a scale of 1:50,000. In this study, the taxonomic pedodiversity was quantified. Taxonomic richness, Shannon's entropy and quadratic entropy have been determined at the WRB reference group level. The indices have been calculated at national, regional and local scales. Regional values have been determined for the 43 soil map sheets and 26 agro-bioclimatic zones of the country, and reveal regional differences in pedodiversity. The local pedodiversity has been determined using a moving window of 11 cells after rasterizing the soil map to a resolution of 90m. Rwanda is characterized by a large overall pedodiversity with the occurrence of 18 soil reference groups. Shannon's entropy (2.05) and evenness index (0.71) suggest a moderate pedodiversity. The average normalized taxonomic distance is quite high (0.69), reflecting the presence of reference groups that are taxonomically quite distant, whereas quadratic entropy reduces to 0.50. The relationship between aerial extent of the region under consideration and various pedodiversity indices, as reported by other authors, has been tested in Rwanda using the regionalized pedodiversity data. These regional differences in local pedodiversity are studied in more detail since insights in the spatial variation in pedodiversity within the country can be used to efficiently target further soil research activities.

PEDODIVERSITY ANALYSIS: STATE OF THE ART AND NEW CHALLENGES

Ibáñez Juan-José^{*[1]}

^[1]Consejo Superior de Investigaciones Científicas~Universidad de Valencia ~ Valencia ~ Spain

In the last years several researches have proposed different concepts and mathematical tools in the frame of pedodiversity (a neologism of soil diversity) studies. Some of them fail to defend their proposals when claiming that their suggestions are better than the previous ones. Along the 1960ies and 1970ies, ecologists also published several novel indices and definitions of “ecological diversities”. Recently, theoretical ecologist auto-criticized this plethora of indices and definitions as it generated big confusion and issues when comparing different studies. Similar problems, due to the proliferation of indices and concepts, begin to affect pedodiversity studies. The soil cover is very complex (as biocenoses, ecosystems, etc.) to have a unique definition and index in order to measure its diversity. As matter of fact, in pedodiversity studies several approaches, definitions and mathematical tools, with their respective pros and cons, are present, as well it occurs in biodiversity studies. Definitions do not say anything if they are not operationalized using robust scientific mathematical tools. Often the definitions and indices more complex are no better than the simplest. Different objectives demand different approaches. If the results obtained in different studies can not be compared, it will be impossible any progress in assessing pedodiversity patterns and regularities of the pedosphere.

**PEDOSITES AS AN ELEMENT IN ASSESSMENT OF SOILSCAPE AND ECOTOURISM
POTENTIAL: A STUDY IN A DESERT ECOSYSTEM OF NORTHERN CHILE.**

Sepúlveda-Varas Alejandra^{*[1]}, Muñoz-Pedrerros Andrés^[1]

^[1]Universidad Católica de Temuco ~ School of Environmental Sciences ~ Temuco ~ Chile

The highland (Puna) of northern Chile, Atacama region, is an ecosystem located over 4.000 m.a.s.l.; in the high peaks and with a history of active volcanism. The lagoon Lejía is in a depression desert, with a high steppe climate (low temperatures and strong daily oscillation, rainfall concentrated in summer, high evaporation and low relative humidity). The area in which it is inserted lagoon Lejía is near one of the three sites of international interest for tourism in Chile. The objective of this study was to evaluate the potential of the lagoon Lejía for the development of ecotourism activities with particular relevance in the identification and assessment of pedosites, generating information with multicriteria GIS cartographic expression (including geodiversity, pedodiversity, landscape and biodiversity). Pedosites were identified and evaluated as part of soilscares and fragile environments associated with initial development, using criteria adapted from those used for geosites. The visual landscape quality was evaluated by direct assessment of representative subjectivity and indirect analysis using a standardized panel of evaluators. The flora and vegetation was evaluated with phytosociological surveys describing 29 species of two plant associations. The fauna is evaluated using a variety of field census methods (traps, camera traps, and acoustic surveys) recorded 39 species of vertebrates. Finally, we generated a geodatabase which was integrated in GIS to generate categories of use of the landscape with ecotourism potential.

MAKING SOIL MAPS WITH WRB: THE GUIDELINES (2010)

Schad Peter^[1], Spaargaren Otto^[2], Micheli Erika^[3], Eberhardt Einar^[4]

^[1]TU München ~ Soil Science ~ Freising ~ Germany ^[2]ISRIC ~ ISRIC ~ Wageningen ~ Netherlands ^[3]Szent Istvan University ~ Soil Science and Agricultural Chemistry ~ Gödöllő ~ Hungary ^[4]Federal Institute for Geosciences and Natural Resources ~ Groundwater and Soil Science ~ Hannover ~ Germany

The 2007 edition of the international soil classification system WRB (World Reference Base for Soil Resources) is focused on pedon classification. WRB has two hierarchical levels. The upper level comprises 32 Reference Soil Groups (RSG). At the lower level, adjectives called qualifiers are added to the RSG name. To classify a pedon, all applying qualifiers have to be added. Their sequence is fixed by rules following practical reasons without a hierarchy of importance. This is inappropriate for creating map units. In 2010, the IUSS Working Group WRB published electronically the „Guidelines for constructing small-scale map legends using the WRB“: http://www.fao.org/fileadmin/templates/nr/images/resources/pdf_documents/WRB_Legend.pdf.

Without changing definitions, the qualifiers were arranged differently. For every RSG, there is a small number of Main Map Unit Qualifiers which are ranked. All others are Optional Map Unit Qualifiers which are listed alphabetically. The number of qualifiers in the map units depends on the scale. At very small scales, only the RSGs are shown. If the scale is larger, the first applying qualifier of the main list is added, at the next larger scale the first two, etc. They are placed before the name of the RSG. At every scale, additional qualifiers may be added in brackets behind the name of the RSG. They may stem from the main list (not yet used for that map unit) or from the optional list. Besides the dominant soil, co-dominant and associated soils can be shown. Example maps at different scales of the sheet Flensburg (Germany) will be presented.

Within the European Union, there is a general interest to prepare joint soil maps at a 1:250000 scale in order to harmonise agricultural and environmental policies. The World Reference Base for Soil Resources (WRB) has been adopted as the common soil classification system within the EU. As soil surveys in most member states were conducted independently, the challenge is now to convert the national legends into a common WRB legend. Based on our experiences from converting the legend of the Soil Map of Belgium to WRB, we discuss the strengths and constraints of using WRB for both large scale (1:50000) and small scale (1:250000) maps. By using WRB Reference Soil Groups with one or two main qualifiers, the principal soil information of the original 1:20000 scale Soil Map of Belgium can be represented. Inevitably the conversion to WRB leads to some loss of information as details on soil texture, drainage and substratum get generalised into broader categories in WRB. This generalisation however can be neatly presented on 1:50000 scale maps. Being less complex than the original maps, these maps have the advantage to provide better insights into the regional soil geography. Moreover, as they are built on international classification concepts, the historical soil maps are made accessible to a wider audience. The conversion into WRB units also allowed for a straightforward generalisation and production of small scale maps (1:250000) which should be suitable for producing a soil map at European level.

S02.04 -3

USING WRB TO MAP THE SOIL SYSTEMS OF ITALY

Costantini Edoardo*^[1], Magini Simona^[1], Barbetti Roberto^[1], Labate Giovanni^[1], Fantappiè Maria^[1]

^[1]CRA-ABP ~ Centro di ricerca per l'agrobiologia e la pedologia ~ Firenze ~ Italy

Aim of this work was to test the 2010 version of the WRB soil classification for compiling a map of the soil systems of Italy at 1:500,000 scale. The source of data was the national geodatabase storing information on 1,414 Soil Typological Units (STUs). Though, basically, we followed WRB criteria to prioritize soil qualifiers, however, it was necessary to work out an original methodology in the map legend representation to reproduce the high variability inside each delineation meanwhile avoiding any loss of information. Each map unit may represent a combination of three co-dominant STUs at the most. Dominant STUs were assessed summing up the occurrence of STUs in the Land Components (LCs) of every soil system, where each LC is a specific combination of morphology, lithology and land cover. STUs were classified according to the WRB soil classification system, at the third level, that is, reference soil group and first two qualifiers, when possible. Since the large number of delineations, map units grouping was needed to make the map more legible. Legend colours were organized according to soil regions groups firstly, then by considering the highest level of soil classification, so resulting a nidificated legend. The map showed 3,357 polygons and 704 map units. The most common STU were Calcaric Cambisols, by far followed by Calcaric Regosols, Eutric Cambisols, Haplic Calcisols, Vertic Cambisols, Cutanic Luvisols, Leptic Pheozems, Chromic Luvisols, Dystric Cambisols, Fluvic Cambisols, and others STUs belonging to almost all the WRB soil references. Keywords: geodatabase, soil systems

S02.04 -4

SOIL CLASSIFICATION AS A TOOL TO PRODUCE USER-FRIENDLY THEMATIC SOIL MAPS IN NORWAY

Nyborg Aage^[1], Solbakken Eivind^[1], Svendgård-Stokke Siri^[1]

^[1]Norwegian forest and landscape institute ~ Soil section ~ Norway

The soil mapping program in Norway started in the early 1980s. The purpose was to provide detailed and standardized data on soils as a resource, to enable the optimal utilization of the cultivated land and to be able to evaluate the environmental costs of modern agriculture. All soil maps are accessible on the internet at no cost. An adapted version of WRB, adjusted for Norwegian soil conditions, has been used as a basis for soil mapping in Norway since the turn of the millennium. Older soil maps have also been correlated into this soil classification system, which uses WRB-qualifiers that are important for Norwegian agriculture. The WRB-qualifiers proved to be a good starting point for deriving thematic soils maps. The qualifiers were given values from 0 to 1 according to the degree of limitation they represented for different uses of the soil. Different indexes were calculated for each soil type depending on soil use, with 100 as top score (no limitations). Suitability maps were then derived using the indexes and other information from the soil map signatures. The resulting thematic soils maps ranges from a general suitability for agriculture to suitability maps for different crop types. Other thematic maps focus on specific limiting factors such as soil drainage and risk of draught. All maps are user-friendly with easy to understand legends. They also serve the purpose to provide users outside the soil science profession with the useful information which is hidden in soil classification.

S02.04 -5

WEAK POSITION OF SOIL TROPHIC STATUS IN WRB MAKE DIFFICULT A CLASSIFICATION AND CARTOGRAPHY OF CAMBISOLS

Kabala Cezary^[1], Bozena Smreczak^[2]

^[1]Wroclaw University of Environmental and Life Sciences ~ Institute of Soil Science ~ Wroclaw ~ Poland ^[2]Institute of Soil Science and Plant Cultivation ~ Department of Soil Science ~ Pulawy ~ Poland

Base saturation is now inconsistently used as a diagnostic feature in WRB classification. On one hand it serves to separate the key diagnostic horizons (e.g. mollic and umbric), and to identify (e.g. Phaeozems) or distinguish the reference soil groups (e.g. Luvisols versus Alisols). At the same time, however, the eutric and dystric qualifiers are located not among “prefixes”, but in distant places on the list of “suffixes”, which significantly diminishes their rank in the RSG name. Meanwhile, in the weakly-developed soils, especially in Cambisols and Arenosols, but also in Fluvisols, Gleysols and Histosols, the trophic status is strongly related to the conditions of soil formation and determines their environmental functions and productivity (e.g. in forestry). It is therefore of primary importance for the correct classification of soils and proper delimitation of soil variability on the soil map. We postulate, therefore, to place the eutric and dystric qualifiers in the list of “prefixes” directly before haplic qualifier. The presentation will be illustrated with the results of two case studies on Cambisols developed in different geochemical environments of the southern Poland.

IRISH SOIL INFORMATION SYSTEM – VALIDATION OF DIGITAL SOIL MAPPING USING TRADITIONAL SOIL SURVEY.

Creamer Rachel^[1], Constanje Ron^[2], Schulte Rogier^[1], Reidy Brian J*^[1]

^[1]Teagasc ~ Soils, Environment and Land Use ~ Wexford ~ Ireland ^[2]Cranfield University ~ National Soil Resources Institute ~ Bedford ~ United Kingdom

The Irish Soil Information System project is a national soil mapping programme to assess the distribution of soil types for Ireland and construct a soil map, at 1:250,000 scale. This is in response to national requirements to address the need to provide soil with a level of protection similar to for water and air and, at international level. The work being undertaken in this project moves a National soil classification system into a new digital generation. This work is ground-breaking, as no other country has adopted such a complementary approach of combining novel digital techniques with groundtruthing using traditional soil survey methodologies at a National scale. Digital physiographic models have been applied to generate soil-landscape models to allow the development of a predictive soils map for areas not previously surveyed in Ireland. This map has been interrogated using traditional field soil survey techniques, since 2010 and detailed field assessment will continue until November 2012. Validation of the digital soil maps using the augerbore records (>5,000) from 6 counties allows for the comparison of digital soil maps and traditional soil survey techniques in assessing key features such as 1) recognition of diagnostic features in a landscape, 2) landscape attributes in determining soil sub-groups 3) the divergence of that seen in the field compared to that predicted using spatial landscape models. The outcomes of this validation exercise will provide a robust assessment of the application of digital soil mapping techniques compared to soil survey at understanding soil-landscape relationships.

ANTHROPOGENIC IRON OXIDES IN SOILS - A BASIS FOR POLLUTION STUDY IN ORE MTS, CZECH REPUBLIC

Kapicka Ales^[3], Lukesova Veronika^[2], Petrovsky Eduard^[3], Grison Hana^[3]

^[1] ~ geomagnetic ~ Prague ~ Czech Republic ^[2] Czech University of Life Sciences Prague ~ Soil Science and Soil Protection ~ Prague ~ Czech Republic ^[3] Institute of Geophysics ASCR ~ geomagnetic ~ Prague ~ Czech Republic

We have investigated magnetic properties of depth soil profiles from Ore Mountains (Czech Republic) which belong to a highly contaminated, so called Black Triangle in central Europe. Emission level is strongly affected by considerable concentration of big sources of pollution (power plants burning fossil fuel, metallurgical and chemical industry). Average annual concentration of PM₁₀ (35-46 µg/m³) in the area of Ore Mts foothills belongs to the highest within the Czech Republic. In localities across the investigated region, increased values of magnetic susceptibility (25 – 200 x 10⁻⁵ SI) were clearly identified in the top-soil layers. At the same time, other magnetic parameters such as frequency dependent magnetic susceptibility k_{FD} and IRM acquisition or AC demagnetization curves indicate that the accumulated anthropogenic ferrimagnetics dominate these layers. Magnetic enhancement is limited to depths of 4-7 cm below the soil surface, usually in F-H or top of Ah soil horizons, deeper soil horizons are characterized by much lower values of susceptibility (up to 30 x 10⁻⁵ SI). We will show that significant magnetic parameters (hysteresis parameters, k_{FD}, T_c) and SEM results of contaminated topsoils are comparable with magnetic parameters of atmospheric dust, collected (in high volume dust samplers) at the same localities. In situ measurements of topsoil magnetic susceptibility were used to compile a 2-D map, which represents distribution of atmospheric dust deposition in the Ore Mountains region and outlines areas of increased soil contamination, resulting from local pollution sources.

CHARACTERIZATION OF PEDOGENIC FE/MN CONCRETIONS AND COATINGS IN REDOXIMORPHIC SOILS

Händel Matthias^{*[1]}, Rennert Thilo^[2], Totsche Kai U.^[1]

^[1]Friedrich-Schiller-Universität Jena ~ Lehrstuhl für Hydrogeologie, Institut für Geowissenschaften ~ Jena ~ Germany

^[2]Technische Universität München ~ Lehrstuhl für Bodenkunde ~ Freising-Weihenstephan ~ Germany

Secondary Mn minerals play an important role in many soil chemical processes such as sorption of metal ions and degradation of organic contaminants. Redoximorphic soils such as Gleysols and Stagnosols are characterized by spatially separated enrichment and depletion zones of pedogenic (hydrous) Fe and Mn oxides, which appear as a result of the periodic change between reducing and oxidizing conditions. We investigated stagnic and gleyic subsoil horizons developed from loess, Early Triassic sandstone, calcareous gravel and Middle Jurassic loamy sediments with pH values from 3.7 to 7.3. The concretions, coatings and parts of the surrounding matrix were characterized by electron microprobe analysis and polarizing microscopy on thin sections, XRD, FTIR spectroscopy and analyzed for their total element contents and their oxalate- and dithionite-extractable fractions. Diffractograms and FTIR spectra exhibited showed a signal overlap of clay and Mn minerals. Nevertheless, birnessite was detected in a gleyic horizon (pH 7.3). Backscattered electron images and EDX measurements showed that Mn phases in stagnic horizons always occur together with clay minerals in a matrix. Iron precipitates are partly present in a clay matrix like Mn phases and also as pure Fe precipitates at the edges of pores inside the concretions. Concretions formed in Middle Jurassic sediments showed a shell-like structure, which suggests periodic formation processes. In contrast, concretions developed in stagnic horizons from sandstone were formed by the flow of the soil solution into the interior of aggregates, where Mn phases precipitated. All pedogenic Mn precipitates were enriched in Co, Ni, and As.

S02.05a -3

IRON(III) (HYDR)OXIDE-ORGANIC COPRECIPITATES – FROM STRUCTURE TO REACTIVITY

Freund Anja*^[1], Mikutta Robert^[1], Guggenberger Georg^[1]

^[1]University of Hannover ~ Soil Science ~ Hannover ~ Germany

Iron(III)(hydr)oxide-organic-matter associations (FHO-OM) in soils play an important role in the biogeochemical cycling of iron (Fe), carbon (C), and of nutrients. Such associations are assumed to result from adsorption of organic matter to Fe oxides. However, a second, often neglected pathway involves the precipitation of Fe(III) hydrolysis products in the presence of natural dissolved organic matter and other solutes such as aluminum (Al). Thus, FHO-OM complexes might differ from pure FHO-phases in their structure, composition, and consequently in their biogeochemical reactivity. At present, it is unknown which factors control the composition of FHO-OM coprecipitates and how the structural properties translate into the cycling of the FHO and OM component involved. The objectives are thus to elucidate (i) the structural properties of FHO-OM coprecipitates at different initial Fe:C ratios, initial Al:Fe ratios, and organic matter types, and (ii) the subsequent stability of FHO-OM coprecipitates against ligand-induced dissolution. The structure of FHO-OM phases was characterized by Mössbauer spectroscopy, transmission electron microscopy, X-ray absorption spectroscopy, and selective extractions; the latter to determine the amount of organically complexed Al. The selective precipitation of certain OM components under the variable experimental conditions was shown by pyrolysis gas chromatography. Kinetic dissolution experiments with oxalate and ascorbate were conducted to determine the initial dissolution rates and the extent of dissolution. These parameters were related to the FHO structures in order to elucidate the factors controlling the stability of the mixed FHO-OM phases.

S02.05a -4

INVESTIGATIONS ON THE STABILITY OF SUPERPARAMAGNETIC MINERALS IN SOILS AND ROCKS

Preetz Holger^[1], Christian Rolf^[2], Jan Igel^[3]

^[1]Leibniz Institute for Applied Geophysics ~ Geoelectrics and Electromagnetics ~ Hannover ~ Germany ^[2]Leibniz Institute for Applied Geophysics ~ Petrophysics and Borehole Geophysics ~ Hannover ~ Germany ^[3]Leibniz Institute for Applied Geophysics ~ Geoelectrics and Electromagnetics ~ Hannover ~ Germany

Today, the presence of ultrafine grained, superparamagnetic (SP) minerals in soils as indicated by frequency dependent (FD) magnetic susceptibility is widely used as evidence for soil formation processes. However, SP minerals can also be of lithogenic origin. They occur in magmatic rocks or pyroclastic materials and they may be detritally enriched in soils. In many studies citrate/bicarbonate/dithionite(CBD)-treatment is used to separate lithogenic and pedogenic SP components of soils. We started a comparative study on the chemical stability of SP minerals from 3 rock (2 tuffstones, 1 rhyolite) and 4 soil samples from different climate zones and with different bedrocks. All samples feature noticeable FD susceptibility and were subjected to reductive atmospheres by means of oxygen-free water and by sodium sulphide providing reductive conditions similar to the field. Mutations in magneto mineralogy were controlled by regular measurements of FD susceptibility over a nine-month period. All but one sample remained unaffected suggesting that chemical stability of lithogenic and pedogenic SP minerals is comparable. One humous soil sample displayed a significant increase in SP minerals, which can be explained only by activity of anaerobic dissimilatory bacteria. The observation is ongoing. Additionally, CBD treatment is applied to the samples before and after reduction. Temperature dependent susceptibility measurements ($K_{\text{para}}(T)$) were performed at the beginning of our test series. These measurements will be repeated at the end of the study to clarify changes of the ferrimagnetic composition and grain size by reduction as well as the effects of CBD treatment.

MERCURY MOBILIZATION IN FERRALITIC SOILS UNDER REDUCTIVE CONDITIONS

Bousserrhine Noureddine^[1], Vanessa Alphonse^[1], Mohamad Fakih^[1]

^[1]Faculté des Sciences et Technologies- University of Paris 12, 61 Avenue du Général de Gaulle, 94010 Créteil, France
~ BIOEMCO IRD-UMR 7618, Equipe IBIOS ~ Créteil ~ France

The biogeochemical cycle of Hg in ferralitic tropicals soil is considered still poorly understood. While, several studies demonstrated that in these soils and under anaerobic conditions, the mobility of heavy metals was correlated to dissolution of iron oxyhydroxides and the degradation of organic matter, there is a lack of information about the importance of these processes on mobility of mercury. Little is available too about the role of anaerobic bacteria on the observed solubilisation. In this context, samples of ferralitic soils originating from French Guyana and containing mercury were incubated in batch reactor in presence of growth medium under standard anaerobic conditions. During incubation, bacterial metabolism and metal solubilisation (FeII, FeT, HgT) were followed. Results obtained showed that at the beginning of incubation, a small amount of mercury was solubilised while any bacterial developpement was detected. This mercury was associated to exchangeable phase of soil. A significant solubilisation of mercury was then observed concomitantly to bacterial reduction of amorphous iron oxides. At the end a last part of mercury is solubilised concomitantly to bacterial solubilisation of crystallized iron oxides and organic matter degradation. Our study demonstrated that in anaerobic conditions like those encountered in hydromorphic ferralitic soils, autochthonous bacteria solubilize iron oxide and degrade organic matter liberating associated mercury and rendering it bio-available for further bacterial transformation such as methylation and accumulation along the food chaine.

PATTERNS OF ORGANIC ACID EXUDATION OF PIONEERING FUNGI FROM A GLACIER FOREFIELD

Brunner Ivano*^[1], Goren Asena^[2]

^[1]Swiss Federal Research Institute WSL ~ Forest Soils and Biogeochemistry ~ Birmensdorf ~ Switzerland ^[2]University of Guelph ~ Department of Plant Agriculture ~ N1G 2W1 Ontario ~ Canada

*Fungi, isolated from fine granitic sediments in front of the Damma glacier in the central Swiss Alps, have the capacity to exude organic acids and dissolve granite materials. In particular the zygomyceteous species *Mucor hiemalis* and *Umbelopsis isabellina* and the ascomyceteous species *Penicillium chrysogenum* showed a high capacity to exude citrate, malate and/or oxalate. In this study, we investigated the capacity of these fungal species to exude the organic acids in dependency on the available carbon source. As carbon source we used potentially naturally occurring carbon sources such as dried and powdered cell wall components, bee pollen, green algal cells, cyanobacteria thalli, and fungal mycelia. The patterns of the exuded organic acids will be presented and discussed, and put in relation to the capacity of the fungal species to weather granite materials.*

Soil mycorrhizal fungi act through biochemical interactions at nanometre scale to dissolve minerals and transport weathering products to plant symbionts through metre-scale mycelial networks. Previous research within our consortium project has shown convincingly the nanoscale weathering of minerals by hyphae in direct contact with minerals [1], and at the same time the transport and redistribution of mineral- and plant-derived nutrients (carbon, phosphorus) within the rhizosphere and the plant itself [2]. A key factor in this biologically-driven weathering system is the relationship between the energy supplied from the plant to the mycorrhiza, and the rate of weathering of minerals. Critically, what is the nature of the feedback between the plant root and the distal hyphae that controls allocation of photosynthate within the mycelial network in response to nutrient uptake? Here, we present the results of numerical modelling and simulation of hypha-mineral weathering and hyphal network growth which couples a mechanistic model of element release from minerals to potential fluxes of carbon and nutrient to the plant root from the whole mycelium. Our models indicate that the efficiency of mycorrhizal weathering is sensitive to both geochemical and biological parameters and suggest that local variations in weathering efficiency drive hyphal growth behaviour (e.g., exploratory vs. exploitative) and photosynthate demand. Ectomycorrhizal (EM) fungi increase nutrient uptake by trees in boreal forests. Nutrient deficiency leads to increased carbon allocation to the EM fungi to increase the uptake of nutrients, particularly those of low mobility. Growth and composition of EM communities might differ depending on amount of carbon allocated down to the ECM fungi. We have analysed the EM biomass and community structures at three locations with different nutrient statuses due to different bedrocks, in the Czech republic. The bedrocks were granite, low in Mg, serpentinite, low in P and K, and amphibolite with all nutrients at sufficient level. Sand filled mesh bags amended with apatite (P source), biotite, (K source), hornblende (Mg source), or unamended as controls, were planted in the organic horizon to measure the influence of these minerals on EM growth and on the composition of the EM communities in the sites with different bedrocks. The bags were harvested after 4 or 15 months. We analysed EM growth by measuring ergosterol content in the samples. Community structure were analysed by sequencing mycelia collected from the mesh bags. We found that EM growth was higher in the serpentinite site both after 4 and 15 months while the granite sites showed significantly lower EM growth. Apatite enhanced EM growth in serpentinite site while other amendments had no effect. Another experiment (over 5 years) showed that P deficiency enhanced carbon allocation to EM fungi colonizing apatite amended mesh bags, but the increased carbon allocation did not influence the composition of the EM community.

^[1]University of Antwerp ~ Biology ~ Antwerp ~ Belgium ^[2]Catholic University of Leuven ~ Earth and Environmental Sciences ~ Leuven ~ Belgium

It has been shown that biological silica (Si) cycling controls a large part of the plant-available silica pool in soils, strongly interfering with Si export fluxes to rivers and oceans. In plants, Si is present as biogenic opaline plant structures (phytoliths) –highly soluble compared with mineral silicates-, which return quickly to topsoil after plant death and decomposition. Large biogenic silica (BSi) pools have already been found in forest, grassland and wetland soils. Despite the importance of vegetation for terrestrial Si budgets, only a few studies addressed the imprint of anthropogenic land use changes (i.e. deforestation) on Si pools and fluxes. We show that agriculture and harvest of high Si-accumulating crops (maize, wheat, barley,...) in a temperate European watershed (Scheldt river) constitutes a major flow of BSi out of terrestrial systems, as compared with BSi production in climax forest and grasslands. In addition, reactivity of biogenic silica and soil-plant phytolith pools are compared between different land use types (forest, pasture and croplands) and between soil horizons. Although the fate of the harvested BSi in croplands is still an enigma, we state that its majority ends up in several sinks, depleting soil phytolith pools even more, and suggest a preliminary life-cycle assessment scheme for BSi in an agricultural watershed. As Si-burial in agricultural sinks directly impacts atmospheric carbon dioxide concentrations and diatom production rates in the ocean, a thorough understanding and quantification of the agricultural silica loop is required.

Most cereals accumulate Si in their shoots. Soil bioavailability of Si may be a constraint on the beneficial role of silica in cereals but it is not yet well supported by field data. The aim of this study is to evaluate the long-term impact of wheat straw exports on the pool of soil phytoliths, which, it is suggested, represents the most labile and renewable pool of soil Si. We measured the amorphous Si (ASi) in soils from several experiments at Rothamsted Research (UK), which provided long-term soil data back to the middle of the 19th century, using two alternative extraction techniques: Na₂CO₃ (referred to as ASnc) or zinc bromide extraction (referred to as ASizb). All samples showed a similar range of ASnc and ASizb but low values (0.1- 3.4 mg g⁻¹ DW) compared to published data on natural ecosystems. In the Broadbalk experiment, a decrease over time in ASi in the topsoil samples is in good agreement with the hypothesis that cropping and exports of straw leads to depletion of soil phytoliths. A decrease in Si concentration in straw samples was observed between 1883 and 1944. From 1944 to the present, Si concentration increased irregularly in the straw, probably as the result of liming, which enhanced the dissolution of the remaining phytoliths through increasing pH. Our results therefore support the hypothesis that export of wheat straw leads to a decrease in bioavailable Si.

The silica cycle is an important biogeochemical cycle. In the oceans, silica is essential for diatom growth, which represents 50% of phytoplankton biomass in today's ocean. Permanent burial of diatom C yearly accounts for about 25% of all human CO₂ output. Silica sources for the ocean and the coastal zone coming from continental fluxes to rivers represent 80% of the total inflow. Besides primary and secondary minerals, silica is also present in soils in the biogenic form of phytoliths which have a solubility rate almost one order of magnitude higher than minerals, contributing more to availability of dissolved silica in a shorter time frame. Although the BSi has been intensively studied in marine sediments, only a few studies did the same for the BSi in terrestrial soils. In this work we collected samples from soils with different land uses and locations and analyzed them by carrying out a continuous extraction of silica and aluminium. The BSi content was determined with: 1) the Kamatani and Oku (2000) approach using aluminium correction ; 2) Koning et al. (2002) approach using mathematical models; 3) a new model that splits the silica curve in two parts; and 4) DeMasters (1981) approach. Results showed that the Kamatani and Oku approach is not suitable for soil samples, while the DeMasters technique mostly underestimates BSi content. The application of mathematical models to silica curves provides a new possibility to study the changing silica reactivity through the soil profile and link this to processes occurring in different horizons.

Soil compaction is a key issue in forest soils, and it is suspected of dramatic impact on earth environment. Estimating the compactness, the natural recovery rate, and understanding their factors are, therefore, essential. In the literature, sampling the soil for bulk density at standard water content is recommended, and several techniques such as penetrometer measurements are experimented. These techniques, however, often fail to make diagnosis. On another side, new result and new techniques on the relationships between soil bulk volume, soil constituents, and soil water content, are available, based on shrinkage analysis, constituent's analyses and covariance analyses. This was not performed on forest soils, however, and this was the aim of our study. On two acid forest soils sites monitored after soil compaction we show the limitations of diagnosis based on bulk density assessment and mechanical characterizations. The shrinkage analysis of undisturbed soil samples is used together with covariance analysis to overcome these limitations. We show how the soil constituents, namely soil organic carbon, clay content and free aluminium can be taken into account to understand either the compaction observed or the natural recovery rate. The compactness is mostly driven by SOC, and the observed hydro-structural behaviour of the compacted soils fully agree with previously reported laboratory experiments, thus enforcing new conclusions on the structural behaviour of compacted soils, and how it must be characterized. Taking into account the soil volume on the full water content range and SOC are the keys for improved diagnosis

Ecological as well as economical consequences of mechanized harvesting procedures are of great importance in forestry, not only because of an intense increase in machine mass during tree cutting and transportation, but also because of a drastic increase in the stress application due to more pronounced vibration energy created from the harvesting machines themselves. The actual soil stresses and displacements in soil profiles were analyzed to give an overview on the range of possible effects of harvesting/forwarding systems with respect to the changes in soil physical properties of the forest soils at two depths: 20 cm and 40 cm. The maximum vertical stresses for all experiments exceeded always 200 kPa and reached at the 20 cm depth for some vehicles and sequences of harvesting operations 500 kPa or more. To evaluate the impact of soil stresses on soil structure, the internal soil strength was determined by the precompression stress method. Top and subsoil compaction, an increase in precompression stress values in the various soil horizons, deep rut depth and vertical and horizontal soil displacement associated with shearing effects take place and affect the mechanical strength of forest soils. At comparable sites of former forest soil wheeling and harvesting also the processes of soil regeneration after severe compaction were analyzed. Even after more than 20 years we could not proof a significant structure regeneration which underlines the threat of a longterm irreversibility of soil degradation in case of non adjusted landuse and wheeling/harvesting strategies.

S03.01a -3

RECOVERY OF FOREST SOIL STRUCTURE AND FINE ROOT PROPAGATION AFTER COMPACTION

Schäffer Jürgen^[1], V. Wilpert Klaus^[1]

^[1]Forest Research Institute of Baden-Württemberg ~ Soil science and environment ~ Freiburg ~ Germany

In Central Europe, first indications of areal soil damages caused by soil compaction were reported at the beginning of the 1970' shortly after heavy specialized logging machines were introduced into forest practice. Unfortunately no investigation sites were set aside in the past in order to study the restructuring dynamics after compaction. Thus, well documented wheel track situations from practical harvesting operations differing significantly in the time spans of restructuring were used to derive the status of recovery of soil structure and root propagation. At 11 sites on sensitive loamy substrates in Baden-Wuerttemberg, fine root distribution, pore volume, and gas diffusion coefficients were used to characterize the status of recovery from former soil compaction. The time delays of machine impact reached from 6 to 37 years; apart from two sites dating back to the 1960', the machine weights including load exceeded 10 Mg. Even at the sites with the longest period of restructuring, recovery of pore volume and gas diffusion properties in wheel tracks was limited to the first 10 cm to 20 cm. As well as the soil physical parameters, fine root densities proved a regaining of root propagation in the top soil. The density levels for reference and wheel track strata converged. Below that depth, persistence of damage was still high. Summarizing the results from the 11 study sites it can be stated that on sensitive loamy substrates four decades of natural restructuring will not be sufficient for an overall restoration of soil functionality.

Several studies measured the level of compaction in forest soils due to the use of heavy machinery. According to the soil texture and water content, machines mass and traffic intensity, an increase of bulk density in the soil profile may be induced (Ampoorter, 2007, 2010). The aim of this study is to assess the effects of several machines configurations on soil compaction of Rulles forest (Wallonia, Belgium) (beech forest). The soil is a gravelly loam with a good natural drainage. Three trails C1, C2, and C3, with a length of 70 meters long were selected. These trails corresponded respectively to the passage of a harvester Timberjack 810D, a skidder Timberjack 360C and an agricultural tractor with a trailer. In each trail, the number of skidding cycles varied: one pass, 5 and 15 passes. Following measurements were performed in topsoil (10 cm) and in subsoil (40 cm): water content and bulk density. Furthermore, in subsoil, pF and oedometric tests were performed. The results show that, for a moisture content of 35 %, machines passes don't lead to any significant bulk density increase in topsoil. This was not the case for the agricultural tractor which induces 30% bulk density increase in topsoil. On the other hand, in subsoil, machines passes are responsible of a significant increase of precompression stress. The effect of machines on pore continuity was assessed in topsoil by microtomography by X-ray and in subsoil by pF measurement.

Soil compaction affects many physical, chemical and biological processes in soil, potentially leading to environmental and agronomic problems. However, effects of compaction on soil pore functioning are still poorly understood. The objective of the work was to investigate the persistency of subsoil compaction, and to quantify effects of subsoil compaction on soil pore structure and transport processes. We present data from investigations made in 2009, 14 years after compaction. We sampled intact soil cores at 0.3, 0.5, 0.7 and 0.9 m depth that were used to measure water retention characteristics, saturated hydraulic conductivity (K_{sat}), air permeability (k_a) at -6, -30 and -100 hPa water tension, and gas diffusivity (D_s/D_0) at -100 hPa. Gas transport properties were measured in vertical as well as horizontal direction, in order to assess anisotropy. Finally, we studied the flow pattern in the soil profile by means of infiltration experiments with Brilliant Blue dye. Analysis of the water retention characteristics revealed that structural pores were significantly reduced by compaction, with considerable effects on soil functions. We measured consistently lower values of K_{sat} , k_a and D_s/D_0 , respectively, in the compacted treatment at all depths. Compaction significantly modified anisotropy of k_a and D_s/D_0 . Consequently, compaction modified the flow pattern: we observed that solute transport was confined in the upper subsoil, leading to an accumulation of 'perched' water in the topsoil. Our results suggest that subsoil compaction is persistent for at least more than a decade, with negative consequences for important soil pore functions.

**EVOLUTION OF STRUCTURAL PROPERTIES OF AN ARABLE SOIL AFTER COMPACTION
AND DIFFERENT REGENERATION PATHWAYS**

Weisskopf Peter^[1], Keller Thomas^[1], Oberholzer Hans-Rudolf^[1], Rek Jan^[1]

^[1]Agroscope Reckenholz-Tänikon Research Station ART ~ Soil fertility and soil protection ~ Zürich ~ Switzerland

Knowledge on the evolution of soil structure is essential for assessing and improving the sustainability of soil management techniques in relation to soil quality. The evolution of soil structure results in changes of physical, biochemical and biological soil functions caused by modifications of pore space and soil strength. From an agricultural point of view the potential for structure formation and regeneration made possible by adequate agricultural management techniques is important for the improvement of soil quality and the alleviation of damages caused by mechanical impacts of agricultural machines. To obtain quantitative information on structural evolution in field situations, a model experiment was performed at field scale over five years on an arable soil (loamy cambisol). Agricultural management techniques directly (tillage intensity, compaction frequency) and indirectly (rooting: crop sequence, soil moisture status: irrigation) affecting soil structure formation were applied as experimental factors by using typical farm equipment. The rate of regeneration after soil structure deformation was followed in different treatments by measuring parameters characterizing porosity, permeability and strength of soil structure as well as the composition of soil air, either directly in field soil profiles or in soil samples. The results of this experiment show the importance of weather conditions (or climate, respectively) for the extent and the effects of soil deformations, highlight the relevance of interactions between compacted topsoil and non-affected subsoil layers for soil functions, and demonstrate the significance of factors for the regeneration of soil structure, which can only indirectly be influenced by agricultural management practices.

The use of heavy agricultural machinery, climate changes and other factors cause mechanical deformation of the soil humus horizons which often aren't found out by traditional methods of soil physics. Rheological approaches allow to estimate inter-partial interactions, micromechanical behavior and, hence, to receive the information I of soil structure deformations and its consequences. The humus horizons of typical chernozem (Kursk region) of the arable field, an adjoining forest belt, chernozems under fallow during 40 years and under natural oak forest have been investigated. Rotational viscosimeter with the cylindrical measuring device was used to study rheological behavior of soil samples. The preliminary capillary humidified samples were used. Complete rheological curves (direct and return branches) have been received. Dependences of viscosity of soil on speed of shear in half-logarithmic scale have been constructed. The received dependences looked like power-low behavior. The investigated samples on viscosity value have arranged in a following decreasing order: oak forest – a virgin soil – a forest belt - fallow – an agricultural arable land. The strongest inter-partial interactions have remained in soil under oak wood and on a virgin soil. The carbon content in the investigated number of soils decreases in the same order, as well as viscosity. Possibly, the content and quality of organic matter of chernozem soils is the main factor of soil structure stability, but constant plowing and agricultural use have led to the accelerated mineralization of organic substances and accordingly to degradation of soil structure.

SOIL SUSCEPTIBILITY TO DEFORMATION: ASSESSMENT FROM WATER RETENTION CURVE CHARACTERISTICS AT LOW SUCTION

Guy Levy^[1], Mamedov Amrakh^[2]

^[1]Agricultural research Organization ~ Institute of Soil, Water and Environmental Sciences ~ Bet Dagan ~ Israel ^[2]USDA-ARS ~ Engineering and Wind Erosion Research Unit ~ Manhattan, Kansas ~ United States

Soil resistance to deformation (i.e., soil structure stability), describes the ability of the soil to retain its arrangement of solid and pore space (i.e., aggregates and pores) when exposed to external forces (e.g., tillage, cropping, compaction and irrigation). Aggregate stability tests are commonly used to quantitatively express soil susceptibility to deformation. We studied aggregate stability with the High-Energy-Moisture-Characteristics (HEMC) method, where energy of hydration and entrapped air are the main forces responsible for breaking down of aggregates, and aggregate/structure stability is then inferred from changes in the water retention curves (i.e., changes in pore size distributions) at low suction (0-50 mm). The water retention curves were characterized by the modified van Genuchten (1980) model that yielded, in addition to the model parameters (e.g., α and n that represent the location and the steepness of the S-shaped water retention curve, respectively), two soil structure indices, (i) the volume of drainable pores (VDP) and (ii) the modal suction (MS) which corresponds to the most frequent pore size. These parameters and indices were then used to test the impact of agricultural management practices on soil susceptibility to deformation. Results from four case studies on the impact of (i) tillage history, (ii) crop rotation, (iii) irrigation water quality, and (iv) polymer application clearly indicate that the parameters and indices obtained from the HEMC method can identify and characterize, in quantitative terms, the changes in the degree of soil deformation that may result from employing different types of management practices.

**CREEP MOVEMENT ON SLOPES - HOW STRUCTURE, HYDRAULICS AND MECHANICS
INFLUENCE DEFORMATION PATTERNS**

Ould Baba Hamoudy^{*[1]}, Peth Stephan^[1]

^[1]Institute for Plant Nutrition and Soil Science ~ Soil Science ~ Kiel ~ Germany

Soil deformation by shear forces is one of the key factors affecting the development of ecosystems by changing soil structure and pore systems. Natural shear forces due to gravity along slopes are controlled by the inclination of the terrain, material composition and mechanical properties, stratification and hydraulic situation. The objective of this study was to investigate creep movement in an artificial water catchment (Chicken Creek) and to examine its stability in relation to a rising water level. We are also interested in understanding the effect of creep movement on soil development in re-cultivated post-mining landscapes such as the lignite mining district of the Lausitz (Brandenburg, Germany). In order to more systematically understand the interaction between the above mentioned factors a laboratory experiment (soil box) with the dimensions $l \times w \times h = 3 \times 1 \times 1.2$ m was built to simulate the influence of different combinations of hydraulic and mechanical stresses on creep movements. High resolution digital imaging and Particle Image Velocimetry (PIV) were used to measure the small scale deformation patterns. First results showed a vertical consolidation at the beginning of the experiment followed by shear movement parallel to the main slope after the soil was saturated from the bottom. Deformation patterns were very heterogeneous and clearly influenced by the initial soil structure/stratification. Time series analysis provided details on deformation velocities, which decreased over time.

Proceeding deepening and regulation of the waterway are leading to an alteration of the riparian zone of the Elbe estuary and inland. Accumulation and erosion areas are shifted. Due to a naturally given salinity gradient, 3.5‰ in the North Sea to ca. 1.5‰ in the Elbe estuary and <1‰ in the Elbe river, respectively, soil (micro)mechanical stability and is mainly influenced by texture, water content and matric potential, ionic strength (Na⁺, Ca²⁺, Mg²⁺, Cl⁻, CO₃²⁻, SO₄²⁻), resulting osmotic pressure, and organic matter. (1) Zeta potentials (ζ , mV) were derived from particle charge density (PCD) measurements; due to this, particle strength (attractive vs. repulsive forces) on the colloidal scale was determined. (2) Rheometry was applied to achieve micromechanical parameters (particle-to-particle-scale), i.e. storage and loss moduli G' and G'' (Pa), loss factor $\tan \delta$ (G''/G') integral z (dimensionless parameter of quasi-elasticity) and information about the shear behaviour. (3) Dynamic loading tests were performed leading to data of pre-compression stress and mechanical strength on the meso scale (200cm³ structured soil cores). By applying compressibility factor (C_n), data of rheometry (micro scale) and soil meso scale mechanics were linked. Collected data deriving from this approach may deliver important information to classify and estimate the mechanical stability of the littoral zone of the Elbe estuary and river on several scales.

SOIL VULNERABILITY ASSESSMENT IN MOUNTAIN AREAS: THE VAL D'AOSTA EXAMPLE

D'amico Michele^{*[1]}, Stanchi Silvia^[1], Ratto Sara^[2], Navillod Evelyne^[2], Filippa Gianluca^[1], Freppaz Michele^[1], Zanini Ermanno^[1]

^[1]Università di Torino ~ DIVAPRA ~ Torino ~ Italy ^[2]Regione Autonoma Valle d'Aosta ~ Centro Funzionale Regionale ~ Aosta ~ Italy

Mountain ecosystems are highly vulnerable to flash flood phenomena, which can result in sudden soil water saturation and surface erosion. Saturated soils are vulnerable to solifluction and liquefaction, depending on soil plastic properties. Surface erosion and mass movements create serious hazards for the population and the infrastructures: the recognition and mapping of areas characterized by different vulnerability to erosion processes are of primary importance in order to properly manage the land use and the hydro-geological hazards. The study area is the whole Val d'Aosta region, characterized by a wide range of geological substrates, vegetation types, altitude variations and pedoclimates (from perudic in south-east and at high altitude to xeric-ustic in the intra-alpine central valley). All genetic horizons from 150 soil profiles have been described and analyzed (standard chemical analysis and Atterberg limits), in order to understand how pedogenic processes influence soil plastic properties; the results were also statistically correlated with parent material, plant cover, and pedoclimate. Liquid (LL) and plastic (PL) limits are positively correlated with humified organic matter and with pedogenic iron oxides, thus a decreasing depth trend is visible for most kinds of soils (high stability in A and Bs and low in C horizons). Both properties depend on soil pedogenic development degree, which in turn is related with pedo-climate and anthropic disturbances. The parent material is another important factor influencing soil stability: at similar development degree, carbonate and mica-rich soils show much lower liquid (LL) and plastic (PL) limits and much larger depth trends than other soils.

^[1]The James Hutton Institute ~ Soils ~ Aberdeen ~ United Kingdom ^[2]The James Hutton Institute ~ ICS ~ Aberdeen ~ United Kingdom ^[3]The James Hutton Institute ~ Environment ~ Aberdeen ~ United Kingdom ^[4]The James Hutton Institute ~ Environment ~ Dundee ~ United Kingdom ^[5]Scottish Agricultural College ~ Crop & Soil ~ Edinburgh ~ United Kingdom

Soil compaction is considered a serious threat, especially in highly managed agricultural systems. The adverse effects associated with soil compaction are many and include decreases in crop yield and increasing management costs. There is growing evidence that compaction, particularly of subsoils where amelioration is difficult, has been exacerbated by trends towards using larger and heavier machinery. Methodologies for assessing soil compaction risk are needed to reduce this threat and protect soil quality for future generations. An assessment of the risks, however, is hampered by the complex nature of soil compaction, which results from the sometimes poorly understood interaction of various soil physical properties, climatic factors and land management practices. We present here a Bayesian Belief Network (BBN) for assessing soil compaction risk. BBNs are graphical probabilistic models that are effective for integrating quantitative and qualitative information, and thus can strengthen decisions when empirical data are lacking. The developed BBN combines analytical and morphological data from standard soil surveys with qualitative expert knowledge to estimate the soil compaction risk. The BBN structure follows a standard risk assessment approach, where the risk is quantified by combining assessments of vulnerability and exposure. The soil's vulnerability to compaction is determined from inherent soil and site characteristics and from climatic factors influencing the soil water content, while the exposure is estimated from an evaluation of the stresses inflicted by land management. The BBN is applied to quantify and map the risk of compaction for Scotland using data from the National Soils Inventory of Scotland.

MODEL-BASED ASSESSMENT OF EROSION RISKS ON MAN-MADE SLOPES IN RECULTIVATION AREAS

Kunth Franziska^{*[1]}, Schmidt Jürgen^[1]

^[1]TU Bergakademie Freiberg ~ Soil and water conservation unit ~ Freiberg ~ Germany

Regressive open-cast mining and increasing reclamation of closed-down mining areas pose the challenge of a long-term and safe structuring of reclamation areas. Soil erosion by water leads to heavy losses, especially on fragile non-vegetated soils of these areas. Beyond that, erosion-induced discharge of detached dump particles in close-by abandoned open pits leads to acidification of surface waters. Sulfuric acid-formation due to weathering of pyrite-containing lignite burden dumps causes acidification of groundwater, seepage water and surface waters. The weathering products are stored in sediment pores. Detached by precipitation and transported by surface runoff, they are transported into worked-out open cuts. In addition to ground water influence, erosion processes are therefore involved in acidification of surface waters. To date, geotechnical foundations are used for reclamation of former opencast mining areas; for near-surface slope protection an exclusively experience-based guideline exists. Hitherto, a science-based approach to conceptions of near-surface slope protection does not exist. The aim of this study is the development of a reproducible methodology to determine erosion risks on slopes in reclamation areas. Moreover, a standardised technique is developed to plan, dimension and test erosion protection measures. The analyses of the study are based on the event-based physical erosion model EROSION 3D. The widely used model is able to predict runoff as well as detachment, transport and deposition of sediments. Its use and validation ranges from erosion prediction from agricultural land to sediment input into water bodies. In this study special characteristics of coal-containing dump soils (e.g. hydrophobicity) have to be considered.

SLUMPING OF SANDY SOILS UNDER SIMULATED RAINFALL: HOW DOES WATER AFFECT THIS SELF-COMPACTED SOIL DEGRADATION

Hao Hongtao^[1], Hartmann Christian^[2], Richard Guy^[3], Bruand Ary^[5]

^[1]INRA / Agrocampus Ouest ~ UMR SAS ~ Rennes ~ France ^[2]Institut de Recherche pour le Développement (IRD) ~ UMR 211 - Bioemco ~ Paris ~ France ^[3]Institut National de la Recherche Agronomique (INRA) ~ UR Science du Sol ~ Orléans ~ France ^[4]Université d'Orléans, CNRS/INSU, Université François Rabelais de Tours ~ Institut des Sciences de la Terre d'Orléans (ISTO) ~ Orléans ~ France ^[5]Université d'Orléans, CNRS/INSU ~ Institut des Sciences de la Terre d'Orléans (ISTO) ~ Orléans ~ France

The sandy soils can serve as a potential reserve for cultivation. However, they are prone to structural degradation which will limit their already low production potential. One special degradation is slumping, i.e. increase of bulk density (compaction) caused by rainfall or irrigation. A few field experiments have described slumping behavior, but the processes and factors are less clear. Our objective is to identify the processes and factors that affect slumping under simulated conditions. In laboratory, cultivated soil model were built in cylinders (20 cm in height and diameter). Two materials were used: 1) the original soil from one previous field experiment site, and 2) the sand fraction extracted from this soil. These model soils were submitted to simulated rainfalls with different intensities (20 to 120 mm h⁻¹), combined with different suctions (20 to 90 hPa) at the bottom of the cylinder. The slumping for original soil happens when 1) the water potential reached a threshold value near 0 hPa (before full saturation). Here the soil cohesion decreased and a fragile equilibrium conditions were reached according to granular material theory; 2) the potential value was kept long enough and the cohesion continue decrease until equilibrium failed. Surprisingly, no slumping was observed for extracted sand whatever the rainfall intensities and suctions. This demonstrates the particles of clay and silt could highly affect soil stability, even their content was less than 10 percent. To identify techniques that can prevent slumping is still an open question.

There is increasing global concern about soil water repellency (SWR) as a soil degradation process. SWR is a transient property expressed in patchy wetting up behaviour of soils once they dry out below a site- and soil-specific critical water content. It might pose a threat to soil ecosystem services in particular to the regulating services in relation to water and carbon, and food provisioning. The understanding of the economic, ecological and environmental consequences of SWR is very limited. Moreover, we are unable to predict when SWR will occur, or disappear. To improve the knowledge on the extent of SWR in New Zealand, we conducted a survey on its occurrence under pastoral land use. Our survey in the North Island revealed that the phenomenon of SWR is prevalent throughout all regions independent of climate but it is influenced by soil order. Further field and laboratory experiments were conducted to assess how SWR impacts on the soil's buffering for water and the related filtering function of soils, and to assess if SWR compromises productivity. Results show that SWR reduced infiltration rates by up to a factor of 20, induced runoff, and increased the risk of contaminant loss. Pasture growth was reduced between 5 and 20%. Our research demonstrated that all the investigated ecosystem services of soils were affected by SWR. Research is needed to better understand the causes of SWR so that efficient and affordable mitigation strategies can be developed.

ASSESSMENT OF TOPSOIL STRUCTURE DEGRADATION IN A COMPOST-AMENDED SILTY CLAY LOAM SOIL UNDER SIMULATED RAINFALL

Pellegrini Sergio^[1], Andrenelli Maria Costanza^[1], Simoncini Stefania^[1], Vignozzi Nadia^[1]

^[1]CRA ~ CRA-ABP Research Centre for Agrobiological and Pedology ~ Firenze ~ Italy

A mesocosm experiment was set up to assess the effect of different rates of organic amendment addition on topsoil structural properties of a silty clay loam soil prone to crusting. Compost obtained from the organic fraction of municipal solid waste was added for two consecutive years to an Udifluventic ustochrept soil from Emilia-Romagna region (Northern Italy) at rates of 0 (C0), 10 (C10) and 40 (C40) Mg ha⁻¹ y⁻¹. Afterwards, the three soils were subjected to rainfall simulations (47.5 mm in 90 min) to evaluate the effect on soil crusting by quantifying runoff volume, soil loss, soil random roughness (RR), and macroporosity of the surface layer. Soil total organic carbon (TOC) content and loss of dissolved organic matter (DOM) through runoff were also assessed. C10 induced a 34.6% reduction in runoff volume respect to control (C0), while no runoff was observed in C40. A similar decrease (32.9%) was also detected as regards to soil loss. RR values increased from 0.221 to 0.242 and 0.495 cm in C0, C10 and C40, respectively, as a consequence of the lower amount of splashed soil. Moreover, compost addition caused a significant increase of TOC and a 40% decrease of DOM. Overall, even the lower compost addition rate (C10) significantly improved the soil surface response to the applied rainfall energy. These results, and the evidence of an increasing occurrence of heavy rainfall events associated with climate change, stress the importance of contrasting the depletion of organic matter pool in agricultural soils.

EVALUATION OF SOIL EROSION TRENDS TO ASSESS THE SUSTAINABILITY ASSOCIATED TO CROP MANAGEMENT PRACTICES IN SPAIN

Garcia Moreno Rosario^[1], Saa Requejo Antonio^[1], Diaz Alvarez Maria Cruz^[1]

^[1]CEIGRAM - UNIVERSIDAD POLITECNICA DE MADRID ~ EDAFOLOGIA ~ Madrid ~ Spain

Erosion is highly associated to agricultural activities. The increase in crop productivity during the last decades has developed new conservation techniques in order to assure the sustainability of soil. These practices are of great importance mainly in semiarid countries, as Spain, where erosion is one of the biggest environmental issue, especially that produced by water. In order to study the consequences of the increasing productivity in the erosion of soils, the present study evaluated the soil losses related to productivity of most important crops grown in Spain during the last twenty years. The selected indicators estimated the losses in soils as a function of fruit productivity, tons per year per kg, and economical income of produced item. The selected crops were the most significant for all the regions of the Spanish territory. The results showed an improving trend in conservation practices. The studied showed that conservational practices have decreased the losses of soils in an average of 300 t/ha-yr and have increased the production of the studied crops from 1987 to 2007 for the 52 provinces in Spain.

DUST EMISSIONS FROM ARABLE LAND: RELEASING PROCESSES, SOIL DEGRADING EFFECTS AND CONTROLLING FACTORS

Funk Roger*^[1]

^[1]Leibniz-Centre for Agricultural Landscape Research ~ Institute of Soil Landscape Research ~ Müncheberg ~ Germany

Dust emissions from agriculturally used areas cause gradual soil degradation and contribute to air pollution. Soil dust is released by wind erosion, tillage operations or traffic on the fields and its emission is affected by soil properties as texture, organic matter or soil moisture. The aims of our investigations were to quantify the carbon losses by wind erosion, to calculate the emitted dust during tillage operations and to compare the dust composition in relation to the releasing process. The diverse influencing factors were investigated in field and wind tunnel experiments. Effects of soil moisture, temperature and humidity on total dust emissions were investigated after drying the soil in the laboratory and at the field in the diurnal course. The results show the preferred removal of organic matter by wind erosion. Dust trapped in 6 m height showed an enrichment ratio of about 7 for organic matter. A heavy wind erosion event can remove about 500 kg humus per ha. The particle size composition of emitted dust is significantly influenced by the releasing process. Increasing mechanical impact causes more PM_{1.0} emissions, with traffic > wind erosion > tillage. Soil moisture affects the dust emission of sandy soils much more than of fine textured soils. There is a distinct diurnal course of the dust emission, caused by temperature (soil and air) and humidity with a maximum at the early afternoon.

Wind erosion is a major contributor to desertification in the Sahel. So far three effective countermeasures for wind erosion (i.e. ridging, mulching with post-harvest crop residue, and windbreaks) have been proposed. However, they are not practical for Sahelian farmers who are economically challenged and have limited manpower. We therefore designed a new land management practice, "Fallow Band System," which can be used for both controlling wind erosion and improving soil fertility and crop production. This method does not impose additional expense and labor requirements on Sahelian farmers and thus, will be practical for them. The objective of this study was to evaluate the effects of the "Fallow Band System" on wind-erosion control and soil-fertility improvement. We conducted field experiments at the International Crops Research Institute for the Semi-Arid Tropics West and Central Africa and showed that (i) a fallow band can capture 74% of wind-blown soil particles and 58% of wind-blown coarse organic matter, which suggests that it can effectively control wind erosion, (ii) the amount of soil nutrients available for crops in a former fallow band was increased by the decomposition of trapped soil materials, and (iii) the amount of soil water available for crops in a former fallow band was increased by the trapped wind-blown soil materials through improvement of rainwater infiltration into surface soil. From these results, we concluded that the "Fallow Band System" can be useful for preventing desertification and improving soil fertility in the Sahel, West Africa.

^[1]Physical Geography and Environmental Change ~ University of Basel ~ Basel ~ Switzerland ^[2]Physische Geographie ~ Trier University ~ Trier ~ Germany ^[3]Land Degradation and Development ~ Wageningen University ~ Wageningen ~ Netherlands ^[4]Department of Agroecology ~ Aarhus University ~ Aarhus ~ Denmark

Soil erosion by wind and water is able to cause severe soil loss from agricultural fields depending on the erosivity of wind and rainfall as well as the soil's erodibility and the applied land management. Unfortunately, in most experimental field studies the combined effect of both erosional processes is not taken into account. The objectives of this study were therefore, to apply a newly developed portable wind and rainfall simulator (PWRS) on different agricultural soils and to explicitly investigate the importance of wind-driven rain for soil erosion. The PWRS was used on three test sites in Spain, The Netherlands, and Denmark. The test sites differed from crusted silty loam to fine loose sand and leeward slopes from $<2^\circ$ up to 10° . All soils were bare and consolidated. Simulated wind velocity and rainfall intensity was constant through all measurements to enable observation of direct influence of soil characteristics and slope angle. The results show a wide range of soil detachment ranging from zero up to 150 g m^{-2} in 30 minutes. On crusted silty loam soils with moderate slope angle highest erosion rates were measured for rainfall simulations on dry soil conditions. On flat surfaces with loose sandy texture highest erosion rates were reached under wind-driven conditions, exceeding rates under windless conditions up to 10 times. In conclusion, the expected increase of soil erosion on agricultural fields seems very likely is not as clear as expected and seems to be very dependent on soil conditions and slope angle of the surfaces investigated.

TEMPORAL EVOLUTION OF SOIL ERODIBILITY: ASSESSMENT OF EXPLANATORY FACTORS, AND CONSEQUENCES ON EROSION MODELLING. AN EXAMPLE FROM THE BEAUCE AREA, FRANCE

Algayer Baptiste*^[1], Darboux Frédéric^[1]

^[1]Institut National de Recherche Agronomique (INRA), UR 0272 Science du sol ~ UR 0272 Science du sol ~ Orléans ~ France

Soil erodibility is a key parameter in soil erosion models. Usually, water erosion models take erodibility as a constant for a given soil. However, many studies showed that erodibility changes during the year in relationship with climate. If the seasonal trends are recognized, the underlying factors and processes remain unclear. To assess the climatic parameters and soil properties causing these variations, a six-month long field monitoring was conducted in the Beauce area (south of the Paris Basin, France). Samples from two soils (a silty clay loam and a silt loam) and from two topographic positions were collected at two time scales: monthly, and a few days apart during the week following significant rain events. Aggregate stability was used as a proxy of soil erodibility. Other measurements were humidity and temperature of soil and air, organic matter content, soil texture, water content, microbial biomass, hydrophobicity, and soil crusting. Aggregate stability showed large variability at both time scales. After significant rain events, aggregate stability showed different trends depending on soil type, rain amount and topographic positions. These differences in aggregate stability imply different erodibilities. The results clearly contradict the common practice of assigning a temporally and spatially-constant erodibility to a given soil. Soil texture, organic matter and microbial biomass could not precisely explain erodibility changes. However, the post-rain desiccation was significantly related to the erodibility increase at the short time step. This result emphasizes the influence of the wetting-drying cycles in soil erodibility variation.

Soil erosion is a critical driver for desertification in Mediterranean regions, and this problem could be accelerated due to changes in rainfall intensity and vegetation cover caused by climate change. The study of these impacts can be done through the use of eco-hydrological and erosion models, but there is presently a lack of data on erosion rates and processes which limits the applicability of models to these regions. Project ERLAND seeks to address these issues through the intensive monitoring of representative Portuguese agroforestry watersheds. The Macieira de Alcoba watershed (north-central Portugal; 95 ha) is part of this monitoring network. It is located in the Caramulo mountain range, has a wet Mediterranean climate, and is covered mostly by commercial forests (c. 60%) and agricultural fields (c. 40%). Within this catchment, runoff and sediment discharge data are recorded in a representative field and at the catchment scale since the last trimester of 2010. The presentation will focus on the results for the hydrological years 2010/11 and 2011/12 at the field and catchment scales. In particular, an effort has been made to identify runoff and erosion sources and processes in this catchment using (i) runoff and erosion event analysis at plot and catchment scales; (ii) hydrograph separation using electrical conductivity, and (iii) hydrological and sediment connectivity mapping based on topography and land-use. Current results underline the high complexity of runoff and soil erosion processes, mainly due to the complex landcover pattern and the presence of irrigation channel network and terraces within the catchment.

S03.02a -6

EFFECT OF SOIL MANAGEMENT ON SOIL EROSION AND PHOSPHORUS LOSSES

Bechmann Marianne^[1], Kværnø Sigrun^[1], Nemes Attila^{*[2]}

^[1]Bioforsk ~ Soil and Environment ~ Aas ~ Norway ^[2]University of Maryland ~ Plant Science and Landscape Architecture ~ College Park ~ United States

In cereal cropping systems, soil management is a major factor contributing to increased risk of soil erosion, transport of soil particles and losses of particulate phosphorus by water. We present results based on several studies on the effect of soil management on soil and phosphorus losses. Examined soil tillage methods include direct drilling (no-till), shallow cultivation and ploughing. Preliminary results show that, in general, deeper and more intense soil management results in greater soil erosion at the plot scale. The effect of soil tillage on losses of total phosphorus generally follows the pattern of soil losses by erosion, but the relationship between soil tillage and losses of phosphorus are much more complex. Besides using descriptive statistical measures, we used a data mining tool - classification and regression tree analysis (CART) - to explore what geological, climatic and management factors were most influential in determining the success of tillage experiments in terms of reducing soil erosion and associated particulate phosphorus losses.

^[1]Leibniz-Center for Agricultural Landscape Research (ZALF ~ Institute for Soil Landscape Research ~ Muencheberg ~ Germany

In 2007 high frequency storm events set a new record in Brandenburg, E-Germany. Disastrous erosion damages occurred with unknown extent so far, especially in regions with low relief energy. We analysed the causes of these phenomena by dynamic EROSION-3D model coupled with very high resolution digital elevation model (DEM 1) and identified a combined effect of frequent strong rain events, high soil water contents, low soil resistance (weak silty sand), and insufficient soil coverage by the growing crop (corn). Beside these classical drivers we clearly detected structure-related process intensities by using DEM 1: erosion hot spots were observed at sites, where historical agricultural land use left behind a barely visible waved surface structure (“Wölbäcker”) in direction of slope. Only by the combined use of DEM1 with EROSION-3D a very good agreement between observed and modelled kinds of water erosion (gully, rill and sheet erosion) could be achieved. Any other approach failed to simulate observed severe erosion damages.

Field borders induce landscape fragmentation and have an important role on the spatial variability of soil erosion and deposition processes. Vegetated borders affect the hydrological and sedimentological connectivity across hillslopes, and all types of field borders act as lines of zero-flux against tillage translocation. This leads to the development of linear anthropogenic landforms (e.g., ridges-and-furrows, headlands, and lynchets) which will keep evolving after field border removal. This is particularly the case in western Europe where agricultural policy and mechanisation led to the massive removal of field borders through numerous land consolidation schemes (1960 – 1990). The aim of this study is to assess the effect of field borders and their removal on soil redistribution in a cultivated hillslope of the SW Parisian Basin. Recent patterns of soil redistribution are derived from 137Cs inventories and analysed with respect to the different topographical settings, especially linear anthropogenic landforms. Then, erosion and deposition rates are calculated using a conversion model that integrates the dominant processes of soil redistribution over the last fifty years. Results show that areas submitted to intensive erosion or deposition are mainly concentrated on linear landforms induced by field borders. The use of the conversion model highlights that soil redistribution is strongly dominated by tillage-induced processes. Land consolidation enhanced soil redistribution through the conversion of depositional areas into sediment delivering areas. Erosion and deposition processes induced by field borders and their removal appear to be very important when compared to mean soil redistribution in the entire study area.

EVALUATION OF SEDIMENT TRAPPING EFFICIENCIES OF VEGETATIVE EROSION CONTROL STRUCTURES

Verbist Koen^{*[1]}, Vermang Jan^[1], Vanderlinden Bruno^[1], Cornelis Wim^[1], Gabriels Donald^[1]

^[1]Ghent University ~ Soil Management ~ Ghent ~ Belgium

Erosion on agricultural fields in the hilly regions of Flanders has been recognized as an important economical and ecological problem that requires effective control measures. Since 2004 this has led to the implementation of a myriad of field scale solutions, such as erosion control structures or dams made out of vegetative materials. In this study, dams made out of coir (coconut) and wood chips were evaluated on three different levels of complexity. Under laboratory conditions, one meter long dams were submitted to two different discharges and three sediment concentrations under two different slopes, to assess the sediment delivery ratios under variable conditions. At the field scale, discharge and sediment concentrations were monitored under natural rainfall conditions on six 3 m wide plots, of which three were equipped with coir dams, while the other three served as control plots. The same plots were also used for rainfall simulations, which allowed to control sediment delivery boundary conditions more precisely. Results show a clear advantage of these dams to reduce discharge by minimum 49% under both field and lab conditions. Sediment delivery ratios were very small under laboratory and field rainfall simulations (4-9% and 2% respectively), while larger SDRs were observed under natural conditions (43%), probably due to the small sediment concentrations (1-5 g l⁻¹) observed and as such a larger influence of boundary effects. Also a clear enrichment of larger sand particles (+167%) could be observed behind the dams, showing a significant selective filtering effect.

MODELLING THE INFLUENCE OF BIOLOGICAL CRUST ON SOIL EROSION AT THE PLOT SCALE

Cerdan Olivier^[1], Oumarou Malam Issa^[2], Christian Valentin^[3], Jean-Louis Rajot^[4], Jean-François Desprats^[5]

^[1]BRGM ~ RIS ~ Orléans ~ France ^[2]IRD ~ BIOEMCO ~ Niamey ~ Niger ^[3]IRD ~ BIOEMCO ~ Bondy ~ France ^[4]IRD ~ BIOEMCO ~ Créteil ~ France ^[5]BRGM ~ RIS ~ Montpellier ~ France

Biological soil crusts occur extensively in semi-arid regions; in western Niger, they are associated with various types of physical soil crusts in fallows and in the “tiger bush ecosystem” (landscape with a typical banded pattern consisting of densely vegetated bands of small trees and shrubs alternating with bare soil bands). The objectives of this study is: (i) to highlight the relative contribution of biological soil crusts in runoff and erosion on crusted soil in respect with other soil factors, and (ii) to elaborate and calibrate a dynamic erosion model coupling the Shallow Water equations with the Hairsine-Rose model for different sediment size classes. The study is based on runoff measurements performed in situ on ten 1-m² plots under simulated rainfalls. Biological soil crusts capped pre-existing physical soil crusts with a percentage cover between 39 and 80% on structural crusts compared to 4 and 29% on erosion crusts. Calibration is firstly performed on the saturated infiltration capacity of the different crust types using a minimising algorithm where the distance is based on the Nash–Sutcliffe coefficient. The result is that whatever the suction values we find a power relation between the infiltration of BSC and the infiltration of BSC overlying physical soil crusts. The erosion model is also calibrated to take the different types of crust into account. These results will contribute to evaluate the potential role of biological soil crusts in soil and water redistribution modelling in arid environment of western Niger.

RELATIONSHIPS AMONG RUNOFF, LOSSES OF SOIL AND NUTRIENT WITH RAINFALL CHARACTERISTICS AND SOIL MANAGEMENT PRACTICES IN A HILLY VINEYARD (PIEDMONT, NW ITALY)

Opsi Francesca^[1], Biddoccu Marcella^[1], Cavallo Eugenio^[1]

^[1]Italian National Research Council (CNR) ~ Institute for Agricultural and Earthmoving Machines (IMAMOTER) ~ Turin ~ Italy

Runoff and soil losses caused by natural rainfall events were monitored through a 10-years period of observation in three vineyard experimental plots, located in Alto Monferrato, a vine-growing area of Piedmont, NW Italy. The plots are characterized by slope of about 15% and clay soil. Different soil managing practices were adopted in inter-rows of each plot: controlled grass cover (GC), conventional tillage (CT) and reduced tillage (RT). The rainfall characteristics, runoff discharge, concentration in the water of soil and nutrients were measured. More than 150 rainfall events produced runoff, 63 resulted to be erosive and 55 events recorded losses of nutrients. The data set was elaborated to investigate relationships among runoff, soil and nutrient losses, with rainfall amount, intensity and kinetic energy. The amounts of water, soil and nutrients that run away from the vineyard resulted to be differently related to the season, rainfall characteristics, soil surface conditions. Each year, few rainfall events were responsible of most of the annual soil erosion. The collected data showed that the soil management practices have strongly affected runoff and soil losses. Particularly, considering the soil losses and the vine production, the reduced tillage has proved to be the worst practice for managing the inter-rows. Conversely, the grass cover has a relevant role in reducing water (up to 36%) and soil losses (up to 88%), mainly during summer events characterized by high rainfall intensities. The protective effect of grass cover was also noted in the reduction of nitrogen losses, about 60%.

A COMPARISON OF SPLASH EROSION BEHAVIOURS BETWEEN WETTABLE AND WATER REPELLENT SOILS

Ahn Sujung^[1], Hamlett Christopher^[2], Doerr Stefan^[1], Bryant Robert^[3], Douglas Peter^[3], Mchale Glen^[2], Newton Michael^[2], Shirtcliffe Neil^[6]

^[1]Swansea University ~ Department of Geography ~ Swansea ~ United Kingdom ^[2]Nottingham Trent University ~ School of Science and Technology ~ Nottingham ~ United Kingdom ^[3]Swansea University ~ College of Engineering ~ Swansea ~ United Kingdom ^[4] ~ ~ ~ Germany ^[5]Swansea University ~ Department of Chemistry ~ Swansea ~ United Kingdom ^[6]Rhine-Waal University of Applied Sciences ~ Germany

Soil water repellency may enhance detachability of bare soil by reducing capillary forces between particles. Splash behaviour by multiple water drop impacts has been reported to be different between wettable and water repellent soils. Here we examine the impact of single drops in detail to isolate the effect of soil wettability on the behaviour from other factors related to multiple drop impacts. The populations and travel distances of particles detached by individual water drops impacting from 40 cm height were compared between wettable and chemically hydrophobized glass beads (350-400µm) used as model soil material. The individual trajectory of each ejected particle was traced on high-speed video frames (976 frames/sec). A single drop impact generated particle dispersions (splash saltation) rather than ejections entrained by a water droplet (splashing). Twice as many particles travelled further than 1cm from hydrophobic beads (HB) than from hydrophilic beads (HL), resulting in a significantly greater median travel distance for HB than HL (HB: 1.28cm, HL: 1.16cm, $p=0.007$, $dF=7$). The significantly greater average initial velocities of HB particles ($p=1.45E-09$, $dF=737$) led to higher trajectories and greater travel distances despite the significantly lower average ejecting angles ($p=3.6E-09$, $dF=749$) than for HL. This result suggests that hydrophobic soil particles are more vulnerable to splash erosion than wettable ones from the onset of rainfall even before a water film is generated by accumulated rain drops, which reportedly affects the vulnerability of soil to splash. The further displacement of hydrophobic particles seems to be mainly driven by higher particle velocities.

GLOBAL AND EUROPEAN POLICIES FOR PROTECTING OUR AGRICULTURAL LAND FROM EROSION AND DEGRADATION

Montanarella Luca*^[1]

^[1]European Commission ~ Joint Research Centre ~ Ispra ~ Italy

Global soil resources are limited and are under increased pressure by competing land uses. Protecting sufficient agricultural land for feeding the growing global population becomes therefore of primary importance in the immediate future. Governments and international organizations are therefore paying increased attention to this limited natural resource. Only in few countries effective soil protection policies are in place. Therefore there is increased interest in developing transnational soil protection strategies and policies, like the European Soil Thematic Strategy by the EU and the Global Soil Partnership by FAO. The status of these two European and Global policies will be reviewed, including the most recent policy developments.

S03.02c -2

DOES AGRICULTURAL INTENSIFICATION CAUSE TERRACE DEGRADATION?

Schönbrodt Sarah^[1], Karsten Schmidt^[1], Thorsten Behrens^[1], Thomas Scholten^[1]

^[1]University of Tübingen ~ Department of Geosciences, Chair of Physical Geography and Soil Science ~ Tübingen ~ Germany

The effect of bench terraces on the reduction of soil erosion is globally without controversy. However, agricultural intensification and ecosystem changes that currently take place in the Three Georges Region (China) are assumed to reduce the capability of bench terraces to protect the soil against erosion. This terrace degradation is further assumed to enforce the process of soil erosion. Our study aims at the assessment and classification of the different terrace conditions and on the factors triggering terrace degradation by incorporating field mapping and data mining approaches. A total of approximately 1000 bench terraces in the Xiangxi catchment (3,200 km²) was classified according to their condition. The results are: well (14 %) and fairly maintained (39 %), partially (22 %) and completely collapsed (11 %). A sequence of terrace condition is obvious. Overall accuracies of 92 % provide extremely precise information on environmental and anthropogenic indicators affecting terraces in their capability to protect the soil against soil erosion. Mainly anthropogenic-induced effects (e.g., distance to roads, markets, and stream lines) cause the terrace degradation. Also the geomorphic settings (e.g., curvature) affect the terrace condition. However, this effect strongly diminishes against the background of the high land-use dynamics. Our study shows the utmost urgency of understanding the mostly anthropogenic-induced mechanisms of terrace degradation and the process of soil erosion. In a further step, the conceptual TerraCE model was developed in order to transfer the findings onto a larger scale. This enables the consideration of the terrace degradation in soil erosion modeling.

DESERTIFICATION, THE ROLE OF INTENSIVE AGRICULTURE

Eshel Gil^[1], Egozi Roey^[1]

^[1] Ministry of Agriculture and Rural Development, Israel ~ The Soil Erosion Research Station, ~ Emek Hefer ~ Israel

Conventional intensive agriculture is characterized by high productivity, high water use efficiency, longer growing season period, less need for manpower and bare soil. The bare soil concept emerged from the need of crop sanitation and to minimize weeds competition. As a result, it is common to find that large portion of the agricultural area that under conventional management is left bare during the raining season. The coupling of these two characteristic intensify the rain-drop impact that commonly is considered as small scale process. Studies all over the world show that the infiltration rate of bare soil can be decreased by an order of magnitude, or even more, as the sealing layer (commonly named crust) has been developing. When this process is looked as a distributed process over a large agricultural area (watershed, regions) it may lead to large impact on rainfall-runoff relation. This is similar to hydrological regime typically of desert environment where small amount of rainfall with limited infiltration rate produces runoff and flashfloods. Thus agriculture areas in semi-arid and humid environments may behave like a desert land.

S03.02c -4

EFFECTS OF ORGANIC FARMING ON SOIL STRUCTURE AND CROP YIELD UNDER PEA (PISUM SATIVUM)

Garcia Meca Maria Isabel^[1], Klik Andreas^[1]

^[1]University of Natural Resources and Life Sciences Vienna ~ Institute of Hydraulic and Rural Water Management, Department of Water, Atmosphere and Environment ~ Vienna ~ Austria

Agricultural practises, especially under dry conditions, should be managed to protect soil quality and adapt soils to prevent possible negative effects of climate change. The objective of this study was to determine the effect of organic fertilizers on selected soil physical parameters and crop yield. Field experiments were carried out in the Pannonian Basin, northeast of Vienna, Austria. Soil is a chernozem, with 21,9 % sand, 33 % clay, 45,1 % silt and less than 2 % organic carbon. Four farming systems were tested: green manure (G), bio waste compost (C), farmyard manure (F) and biogas slurry (S). Undisturbed samples were taken to measure bulk density, saturated hydraulic conductivity and porosity in two soil depths: 10-15 cm and 25-30 cm. Aggregate stability was determined for surface samples (0-5 cm). Results show significant differences between the treatments. Saturated hydraulic conductivity in the upper soil layer was around 2 times higher in G than all other tested systems. Corresponding to it, lower bulk density is found under G treatment. There were no significant differences of total porosity between the four treatments. Aggregate stability increases in following order: G < F < S < C. Crop yield are higher in S. Combination of green manure with bio waste compost could be an adequate sustainable management to improve soil properties without yield losses under tested conditions.

CONTROL OF SOIL EROSION BY MEANS OF SOD SEEDING IN A MEDITERRANEAN ENVIRONMENT

Cosentino Salvatore Luciano^[1], Scalici Giovanni^{*[1]}, Ambra Riccardo^[1], Guarnaccia Paolo^[1]

^[1]Università degli Studi di Catania ~ DISPA ~ Catania ~ Italy

The research has been carried out over the years 2004-2010 in an area of the internal hill of Sicily region (Enna, c.da Geracello, 550 m a. s. l. 37° 23' N. Lat, 14° 21' E. Long), mainly devoted to durum wheat cultivation, using the experimental plots, established since 1996 on a slope of 26-28%, equipped to determine surface runoff and soil losses. The establishment consists of twelve plots, having 40 m length and 8 m width. In order to study the effect of sod seeding techniques in controlling soil erosion in slopes subjected to water erosion, two plots were not tilled since summer 2004 and plant residues were left on soil surface. In these two plots, annual crops were cultivated. The two plots were compared to several perennial crops and annual crop rotations conventionally sown. The results pointed out that the cropping systems with perennial crops allowed to keep low the soil loss, while annual crop rotation determined a high amount of soil loss. Sod seeding showed promising results also for annual crop rotations.

SOIL EROSION FROM AGRICULTURAL LAND IN THE POLEG CATCHMENT: SOURCES, RATES, MEASUREMENTS AND FUTURE SOLUTIONS

Egozi Roey^[1], Eshel Gil^[1]

^[1]Ministry of Agriculture and Rural Development ~ The Soil Erosion Research Station ~ Emek Hefer ~ Israel

Located at the central costal area of Israel the Poley Catchment is a typical Mediterranean watershed with mean annual rainfall of 550 mm, winter flashfloods and severe soil erosion problems. The soils in the catchment are brown loamy sand to sandy loam soils with potential infiltration rate of 60-80 mm/hr. Of its 135 km², 65% is agricultural land, mainly orchards and row crops (mostly potatoes and carrots). The fields are managed by conventional tillage practices and over the last decade the row crops portion has been increased by 5% and young orchards replaced old ones. As a result of the soil type and the crumbled and bare soil, significant soil losses have been observed. The annual soil loss rate is estimated at 0.007 m. Sediments are delivered to the channel network, in which the fine material (clay and silt size fractions) is transported in suspension and large amounts of well sorted sand (D₅₀ = 0.210 mm) are transported as bedload. As a result river bed is aggrading due to sand bed deposits ranging between 0.2 and >1 m high. However, the cohesive banks of the river remain stable and therefore the incised channels have been mutant into sand bed conduits. This leads to reduction in channel capacity and increasing flood hazards. To solve the problems soil conservations practices must be applied at the catchment scale.

**CONNECTING THE CYCLES: IMPACT OF SEDIMENT, CARBON AND NUTRIENT EROSION
ON GHG EMISSIONS**

Kuhn Nikolaus J.*^[1]

^[1]University of Basel ~ Environmental Sciences ~ Basel ~ Switzerland

The lateral movement of soil through terrestrial ecosystems has been recognized as a significant flux of C within the global C cycle. Soil erosion removes approximately 0.5 Gt of C per year from agricultural land. Much of this C is deposited in the landscape, effectively burying the organic matter and taking it, at least for an unspecified time, out of the C exchange between soil and atmosphere. However, the burial does not consider the full coupling between the biogeochemical cycles. For example, apart from C, nitrogen is eroded and has to be replaced, at least in part, by artificial fertilizers, to maintain soil fertility and dynamic replacement of C. At this point Carbon and nitrogen cycles meet, because the production of fertilizer generates greenhouse gases. The production of one ton of fertilizer generates on the order of 850 kg of carbon dioxide. Applying this number to the 0.5 GT C erosion estimate, the amount of nitrogen lost owing to erosion each year yields carbon dioxide emissions of 0.02–0.04 Pg per year. These emissions correspond to 15–30% of the organic carbon buried owing to soil erosion. In this presentation, the full complexity of biogeochemical cycling on agricultural land is explored and connections between cycles which require consideration for a full GHG emission balance of soil erosion on agricultural land are identified.

**FACTORS CONTROLLING THE QUALITY AND QUANTITY OF SOIL ORGANIC MATTER
AFTER WILDFIRE**

Rumpel Cornelia*^[1]

^[1]CNRS ~ BIOEMCO ~ Thiverval-Grignon ~ France

One of the main fire effects on soils is the alteration of quality and quantity of organic matter input. In general, more than 90% of carbon from the aboveground biomass is lost immediately after fire in form of CO₂. Fire effect on litter layer is dependent on fire intensity. Alterations of organic matter in mineral soil are mainly related to altered input. In addition to reductions of fresh litter input immediately after fire, charcoal, a stable organic matter type, formed through the condensation of labile plant litter compounds and the formation of stable aromatic molecules is usually added to soil. It consists of a continuum of slightly burned plant residues to completely graphitized material. The nature and reactivity of this fire derived organic matter component may depend on precursor material as well as particle size. Coarse charcoal particles are in general characterized by a more stable structure and higher resistance to chemical attack compared to fine ones. The relative addition of coarse and fine particles as will depend on fire characteristics. The OM added to soil after fire is susceptible to be lost from soil either by microbial decomposition or horizontal and vertical transport in solid or dissolved form. I will present examples from different regions and show how fire alters the quantity and quality of soil organic matter and analyze if this has a long-lasting effect on the biological functioning of soil.

CHEMICAL AND MICROBIOLOGICAL PROPERTIES OF SOILS FOLLOWING PRESCRIBED FIRE IN THE ROCKY MOUNTAINS

Prescott Cindy*^[1], Grayston Sue^[1], Switzer Joshua^[1], Hope Graeme^[1]

^[1]University of British Columbia ~ Forest Sciences ~ Vancouver ~ Canada

Thinning followed by prescribed fire is being used to restore forest ecosystems in the Rocky Mountains of North America. We investigated the relationships between fuel loadings (pile size), fire temperature and duration, and changes in selected chemical and biological properties of the underlying soil. Forest floor depth declined from 4.6 to 2.5 cm and consumption was negatively correlated with pre-fire moisture content. Increases in pH and availability of PO₄, Ca and Mg (assessed with plant root simulator probes) were observed in burned plots and were sustained for the first year following fire. Abundances of bacteria (total, gram negative and gram positive, assessed through phospholipid fatty acid analysis) declined in burned plots. Fungal abundance declined in the forest floor of burned plots, but not in the mineral soil. Microbial abundances had not recovered to pre-fire levels one year after fire. In the forest floors, microbial abundances were most strongly correlated with N concentrations prior to fire, and with pH following fire. In mineral soil, microbial abundance was positively correlated with C and N concentrations prior to fire and with N concentrations one year after fire. Litter depth and moisture content were more important determinants of fire effects on soil than was pile size.

TRACING WILDFIRE INTENSITY IN SOILS VIA MOLECULAR PROXIES

Wiesenberg Guido*^[1]

^[1]University of Bayreuth ~ Agroecosystem Research Department ~ Bayreuth ~ Germany

Effects of fire intensity on the chemical composition of charcoal and ash remains have been described recently, which may also alter the chemical composition of soil organic matter (SOM). Such changes have been documented in laboratory experiments e.g. on alkanes, PAHs, BPCA and other molecular markers. This study aims at the investigation of the transferability of such laboratory results to recent grassland, cropland and forest fires, where charred plant residues were sampled from the soil surface and compared to plant biomass and topsoil layers. Chemical composition of wildfire residues corresponded well to laboratory results from low to intermediate fire intensity (<400°C). Compared to living plant biomass a reduction in the amount of extractable lipids and an enrichment in short chain even numbered alkanes was observed, whereas the biogenic signal of long chain alkanes (predominance of odd numbered homologues) was still present. Forest fire residues revealed a stronger enrichment of short chain alkanes compared to grassland and cropland fires, thus suggesting higher burning temperatures. Commonly, topsoil samples (0-2 cm) were characterized by an enrichment of burning residues compared to deeper soil (2-5 cm), except for the investigated oak forest, where a fire occurred ~3 years before sampling. Most likely, the soil was bioturbated, leading to enrichment of burning residues even in slightly deeper soil layers. Temperature influence and composition of burning residues deriving from laboratory experiments were confirmed by samples from natural wildfires. These allow for an assessment of the burning history via SOM, as burning residues might accumulate over time.

MODELING SOIL WATER REPELLENCY IN BURNT HILLSLOPES AND ITS CONSEQUENCES FOR RUNOFF AND SOIL EROSION

Nunes Joao Pedro^[1], Malvar Maruxa^[1], Keizer Jan Jacob^[1]

^[1]University of Aveiro ~ CESAM & Dept. Environment and Planning ~ Aveiro ~ Portugal

Forest fires can enhance soil water repellency and its impacts on soil hydrology and surface runoff generation, with consequences for soil loss. This creates a challenge for hydrological and erosion modeling in burnt forests, since current models do not usually take repellency into account. This presentation focuses on the development and evaluation of an empirical model to predict the seasonal patterns of repellency, and its incorporation in a simple “bucket” model for soil hydrology, runoff generation and soil erosion. The model was developed and tested using data from six eucalypt hillslopes in central Portugal which burned in 2005 and 2006. Data included weekly runoff and sediment collection, and bi-weekly transects detailing soil moisture and water repellency in different parts of the slopes. The sites showed low repellency during the wet winter season and high repellency during the dry summer season, and this seasonal pattern was strongly related with soil moisture fluctuations. Runoff occurred mostly in periods with both high rainfall and repellency, at the transition between the dry and wet seasons; erosion followed runoff episodes. Model development was based on the combined simulation of soil moisture and repellency driven by rainfall and potential evapotranspiration, with repellency limiting the soil water holding capacity. This was applied to a water balance model based on the Thornthwaite-Mather method, using the Morgan-Morgan-Finney approach to estimate runoff and erosion. Results indicate that a simple approach to simulate repellency is feasible and can be included in hydrological and erosion models, improving their performance for burnt hillslopes.

S03.03 -5

ASSESSING THE SIGNIFICANCE OF POST-WILDFIRE SOIL EROSION IN MEDITERRANEAN EUROPE

Shakesby Richard*^[1]

^[1]Swansea University ~ Geography ~ Swansea ~ United Kingdom

Wildfires in Mediterranean Europe are said not only to destroy vegetation and litter, damage property and cause death, but also to cause serious soil loss. This presentation challenges this last view and addresses gaps in understanding. Belief in the seriousness of post-wildfire erosion has led to the view that wildfire is the main agent of Mediterranean soil degradation, apparently supported by much higher post-wildfire erosion rates than those on unburnt terrain. These comparisons, however, mostly exaggerate the former, since erosion rates on the latter are usually extremely low. More meaningful comparisons are needed, but are rare. Soil loss tolerance would theoretically provide a useful comparison, but has been developed mostly for agricultural soils and few estimates relate to Mediterranean-type conditions. An alternative is soil renewal rate, but its determination is difficult as reflected in the few published assessments, and some basic controls are poorly understood. Arguably, comparison with erosion by other disturbance agents (cultivation practices) is the best option. It indicates that Mediterranean post-wildfire soil loss is mostly unremarkable. It is possible, however, that post-wildfire erosion may be (a) directly important in reducing soil quality through preferential loss of organic matter and nutrients, and (b) indirectly important in leading to disturbance by post-fire land management practices that cause significant erosion.

SOIL AS A CARBON STORE: STOCKS AND RECALCITRANCE IN FIRE-AFFECTED AUSTRALIAN FOREST SOILS

Doerr Stefan^{*[1]}, Santin Cristina^[1], Shakesby Richard^[1], Sheridan Gary^[2], Lane Patrick^[2], Hugh Smith^[3]

^[1]Swansea University ~ Geography Department ~ Swansea ~ United Kingdom ^[2]Department of Forest and Ecosystem Science ~ The University of Melbourne ~ Melbourne ~ Australia ^[3]University of Plymouth ~ School of Geography ~ Plymouth ~ United Kingdom

The role of vegetation fires in the global carbon (C) cycle remains unclear. On the one hand, fires emit substantial amounts of C to the atmosphere. On the other, they also transform some of the relatively labile organic C (OC) stored in biomass to more stable pyrogenic OC, which may provide a long-term C sink when accumulating in soils. Here, we present an analysis of OC stocks in Australian forest soils in relation to recent fire history; with a special focus on OC recalcitrance and the relative significance of the pyrogenic OC component in this C reservoir. After the extremely severe '2009 Black Saturday' wildfires near Melbourne, soils were sampled (0-5 cm) at three burnt sites and a long-unburned site in mixed eucalyptus forest, and also at burnt and long-unburned temperate rainforest sites. All were previously affected by wildfire in 1939, with two of the burnt sites also having undergone a fuel reduction burn at different times in the 1980s. OC contents were determined and the OC recalcitrance tested by oxidative degradation (Ascoug et al. 2011, Cosmochim. Acta 75:2361). Three different pools of OC were defined and quantified: labile, moderately resistant and recalcitrant (OC remaining after 24, 100 and 400h oxidation respectively; Masiello et al. 2002, Cosmochim. Acta 66:1025). The results are discussed in the context of fire as a potentially important driver enhancing the stability, and therefore sustainability, of carbon in soil. Funding: NERC grant NE/F00131X/1 and Alfonso Martin Escudero Foundation. We thank C. Sherwin for fire history information.

Many studies developed soil erosion risk modeling methodologies at various scales from regional to Continental scale. The MESOEROS project is the first which aims to understand the soil loss risk on the whole Mediterranean basin for the current climate context and also for the predicting climate changes expected for the 21st century. Two models are used: MESALES (expert rules model) and PESERA (physical based model). Model inputs come from homogenized regional datasets that cover the whole study area. After being calibrated with watersheds data and the PESERA modeling on Europe, the two modeling results are analyzed as well as the model sensitivity to the different input parameters. The modeling validation allow understanding the integration of climate change on modeling results. MESALES and PESERA point out an evolution of the soil erosion risk between the 20th and the 21st centuries around the Mediterranean basin. The two models assess a global augmentation of the soil loss risk at the Mediterranean scale. They both show an increase – in intensity and surface - of the soil erosion risk on areas already sensitive during the 20th century.

^[1]Agricultural University of Athens ~ Soil Science and Agricultural Chemistry ~ Athens ~ Greece

There has been a serious concern about desertification during the last decades, which seems to be a threat for agricultural areas, forests and pastures. Based on existing methodology (MEDALUS research project) the Environmental Sensitive Areas (E.S.A.) of Greece, have been identified. Data for the calculation of indices related to desertification derived from CORINE 2000 land uses, the Soil Associations Map of Greece and series of meteorological data from 97 stations of the Hellenic National Meteorological Service, for the period of 1940 -1970. Geographical Information Systems were used in order to handle and interpret primary data. Theissen polygons created by the 97 meteorological stations were used for the division of Greece in corresponding areas. Each area was classified in zones with a difference of 200m in elevation, to which primary meteorological data were adjusted. Through simple processes in the geodatabase and with the use of the Field calculator tool of ArcGIS 10, meteorological data were translated into E.S.A. climate indices, from which Climate Quality Index (C.Q.I.) was calculated. With the same processes, Soil Quality Index (S.Q.I.) was calculated based on Soil Associations Map of Greece and Vegetation Quality Index (V.Q.I.) and Management Quality Index (M.Q.I.) were calculated based on CORINE 2000. These three levels of information were joined in order to give as a result the E.S.A. Index through geo-processing procedures. The study showed that almost 50% of Greek land was characterized as fragile to desertification, whereas only 6% of Greek land seems to be non-affected by the phenomenon.

KNOWLEDGE OF SOIL WATER BALANCE OF MEDITERRANEAN KARST OF BOSNIA AND HERZEGOVINA IN THE FUNCTION OF WATER CONSERVATION AND PROTECTION FROM EROSION

Custovic Hamid^[1], Misilo Marija^[2], Markovic Mihajlo^[3]

^[1]Faculty of Agriculture and Food Science Sarajevo ~ Soil Science ~ Sarajevo ~ Bosnia and Herzegovina ^[2]Faculty of Science ~ Department of Geography ~ Sarajevo ~ Bosnia and Herzegovina ^[3]Agricultural Institute ~ Soil Science ~ Banja Luka ~ Bosnia and Herzegovina

This study was conducted at the site in Popovo polje, which is one of the typical Dinaric karst poljes, located within the Mediterranean part of Bosnia and Herzegovina (temperature around 14°C and precipitation about 1950 mm). The aim of this work is to shed more light to the relationship between retention, percolation and water runoff and to determine the water balance of soil and its relation to soil erosion in karst conditions. For the purpose of accomplishing this objective the method of lysimeters was applied. The total of six lysimeters with different soil depths (1.3 m, 1 m, 0.5 m, 0.3 m and simulation of karst) was posted. The lisimeters were used in order to study the relationship of precipitation, ET and drainage runoff in the function of soil depth and no-irrigation conditions, aimed to obtain information on the possibilities of restoration of groundwater and surface water. Additionally, a total of six metal cassettes filled with the same soil as in lisimeters were set up to simulate inclination up to 10%, comparative bare ground and ground covered with grass, and to monitor total water runoff and total amount of sediment. The results indicate large differences between the agrohydrological budgets of bare stony soil and loam-clay soils of different depths, while the results of measurements of the total water runoff and amount of sediment indicate that the slope effects can be repaired by grass cover. Keywords: karst, agrohydrology, water erosion, Popovo polje, Bosnia and Herzegovina.

DEGRADATION OF ARABLE LANDS BY URBAN SPRAWL IN LEBANON

Talal Darwish^[1], Ghaleb Faour^[1]

^[1]National Center for Remote Sensing, National Council for Scientific Reserach ~ Soil ~ Beirut ~ Lebanon

Land cover and land use change derived from satellite images are two indicators of land management and land degradation. The Lebanese agriculture sector is facing policy problems, products competitiveness, mismanagement of chemical and water input, land abandonment and the fragmentation of agricultural land under heritage and urbanization. Large land use changes and modifications in the area and spatial distribution of annual and perennial crops have been witnessed for the period span between 2000 and 2010. Comparing land cover map with the expansion of urban settlements between 2000 and 2010, showed a total loss of 308 km² of land resources. Among lands converted into concrete, a total of 194 km² (63%) belong to agricultural fields, 53 km² (17.2%) and 50 km² (16.2%) belong to wood land and grassland respectively. Less than 11 km² (3.7%) of recent urban development has expanded on unproductive land. Simultaneously, in Zahle (Central Bekaa) and Nabatiyeh (South) Cazas a respective loss of 12 km² and 17 km² of arable lands by chaotic urban expansion, expanding from 30 to 42 km² and from 34 to 51 km² between 2000 and 2010 respectively. Chaotic urban expansion leaves a large question mark about the implementation of agro ecological and urban zoning in the country. The low precision from land based statistics indicates the necessity to unify the statistical methods integrally using both remote sensing and land survey as prerequisite to better land resources management.

EFFECTS OF THE RESTORATION ACTIONS TO COMBAT DESERTIFICATION ON SOILS. THE PRACTICE PROJECT STUDY SITE IN PULA (SARDINIA, ITALY)

Zucca Claudio^[1], Fiori Valeria^[1], Cucca Carlo^[1], Musinu Silvia^[1], Campus Sergio^[2], Madrau Salvatore^[1]

^[1]University of Sassari ~ DIT ~ Sassari ~ Italy ^[2]University of Sassari ~ Forestry School di Nuoro (FS) ~ Nuoro ~ Italy

Land Degradation and Desertification affect much of the world's drylands, resulting in a significant loss of biological and economic productivity. Responding to desertification by improving the efficiency of land and resource management represents a crucial step towards social welfare in drylands. However, the evaluation of the actions to combat desertification remains limited. The PRACTICE EC-FP7 project develops and tests integrated evaluation protocols to assess the effectiveness of restoration practices in a network of study sites distributed among the most LD affected regions of the world. In the Pula reforestation area (Sardinia, Italy) integrated evaluation protocols are being applied, based on the unifying conceptual framework provided by the analysis of the desertification impacts on ecosystem good and services and on human well-being, across different spatial scales. The LFA Landscape Function Analysis (LFA) was taken as the reference method to study the effects of the restoration actions on the soils, by comparing different restoration/management actions: i) non-managed area (control area), ii) self-restoration, iii) thinned reforestation, and iv) non-thinned reforestation (to evaluate the effects of the plantation in absence of subsequent silvicultural interventions). The LFA include a range of soil surface assessment indicators to be estimated along linear transects, to derive an Infiltration/Runoff Index, and a Nutrient Cycling Index. In addition, soils were studied and sampled by horizon, and analysed for SOC, pH, N, and other emerging properties. A morphological description of the litter was made, along with a study of the soil microarthropod community.

**INDICATORS OF SOIL AND SEDIMENT LOSS ON A SMALL, DENSELY POPULATED ISLAND:
A CASE STUDY OF MALTA**

Role Avertano*^[1]

^[1]University of Malta ~ Geography ~ Msida ~ Malta

Most regions share common problems when attempting to accurately estimate quantities of soil loss through erosion and this situation is no more real than in Mediterranean islands. This is often due to a gross underestimation of the seriousness of soil erosion and a lack of appreciation of the agricultural sector when compared to more economically significant sectors. In the Maltese case, this problem is compounded by a high population density and sub/urbanization processes coupled with increased environmental pressure and competition from the tourist sector. Soil sealing is accelerating surface-water runoff and the prevailing governmental policy is to facilitate storm water movement through channeling in order to avoid flooding. This has sometimes created hotspots of soil erosion and is also reflected in varying estimates of sediment transport and deposition. Quantitative estimates of soil loss in the Maltese Islands are few and far between. They are also limited to extreme scales: from sets of field studies carried out as academic exercises (limited in time and space) to regional qualitative studies of potential soil erosion risk. This paper focuses on indicators of sediment loss at a drainage basin scale derived mostly from unpublished reports. These can be quite cost effective compared to dedicated long-term studies but they can still offer some potential for effective intervention through policy instruments and provide the basis for a discussion of trends in this phenomenon.

GEOSTATISTICAL MONITORING OF SOIL SALINITY IN UZBEKISTAN BY REPEATED EM SURVEYS

Akramkhanov Akmal^[1], Brus Dick^[4], Walvoort Dennis^[3]

^[1]Center for Development Research (ZEF), University of Bonn ~ ZEF-UNESCO Khorezm Project ~ Urgench ~ Uzbekistan ^[2]Wageningen University and Research Centre ~ Alterra ~ Wageningen ~ Netherlands ^[3]Wageningen University and Research Centre ~ Alterra ~ Wageningen ~ Netherlands ^[4]Wageningen University and Research Centre ~ Alterra ~ Wageningen ~ Netherlands

Soil salinity in the lower reaches of Amudarya is a constant threat. The shallow groundwater table contributes to salinization of the rooting zone which is tackled by leaching at the end or beginning of the vegetation season. However, there is growing concern that the efficiency of the leaching with application of high amounts of water is low. The objective of this study is to monitor the temporal trend of salinity over the three-year period from 2008 to 2010. At the end of the vegetation season soil salinity was surveyed with the electromagnetic induction meter EM38 in vertical dipole mode. The EM device was coupled with GPS. Measurements of ECe were used to calibrate a model for log(ECe) with log(EM) as single predictor. The estimated regression coefficients and their covariance matrix were used to simulate 1000 vectors of regression coefficients. The regression residuals were used to fit a pooled, spatial variogram. This variogram was used to simulate for each year 1000 maps of regression residuals. 1000 maps of ECe for the years 2008, 2009 and 2010 were then obtained by geostatistical simulation of 1000 maps of log(EM) per year, transforming these maps with the simulated regression coefficients, adding the maps of simulated regression residuals, and backtransforming (exponentiation). These simulations were used to derive for each year maps of the predicted ECe and of the probability that ECe exceeds the critical threshold of 8 dSm⁻¹. Besides, a map of the predicted linear trend in ECe was constructed, and of its standard error.

CONSISTENCY OF SOIL PARTITION USING GEOELECTRICAL MEASUREMENTS AT TWO DIFFERENT WATER CONDITIONS

De Benedetto Daniela^[3], Castrignanò Annamaria^[4], Palumbo Angelo Domenico^[5]

^[1]University of Bari ~ Department of Geology and Geophysics ~ Bari ~ Italy ^[2]CRA ~ SCA ~ Bari ~ Italy ^[3]University of Bari "Aldo Moro" ~ Earth science and geo-environmental ~ Bari ~ Italy ^[4]CRA ~ Research Unit for Cropping Systems in Dry Environments (SCA) ~ Bari ~ Italy ^[5]CRA ~ Research Unit for Cropping Systems in Dry Environments (SCA), ~ Bari ~ Italy

Field water content may be highly variable over a range of temporal and spatial scales. Geophysical sensor data can surrogate direct measurement because their outputs depend upon several soil properties, some of them quite dynamic as water content. The objectives of this paper were: 1) to delineate homogenous soil zones by using geophysical measurements and to investigate the consistency of the soil partitioning at two different water conditions. The surveys were conducted in a bare field in south-eastern Italy after an irrigation and in dry condition. GPR at two frequencies, 600 MHz and 1600 MHz, and EMI surveys were carried out along longitudinal and transverse transects and measures with TDR were collected at the intersections of the transects. All data were submitted to geostatistical analysis and were interpolated, using uni- or multi-variate approaches. To obtain spatially contiguous clusters, a clustering algorithm based on nonparametric estimation of probability density function was applied to the multivariate data set of estimated geophysical sensor outcomes, including spatial coordinates after standardization. The consistency of the soil partition obtained at the two different water conditions was computed through confusion matrix and k statistic. The partition of the area in homogeneous zones was different in the two water conditions probing the negative relationship between EMI and GPR data. The confusion matrix showed an accordance between the two cluster maps of only 50%, due to permanent soil properties of the field (i.e. texture), whereas the other 50% of variation was ascribable to more dynamic properties (i.e. porosity).

A LINEAR MIXED MODEL FOR SOIL WATER CONTENT ESTIMATION BASED ON GEOPHYSICAL SENSING: A COMPARISON WITH KRIGING WITH EXTERNAL DRIFT

Cafarelli Barbara^[4], Castrignanò Annamaria^[2], De Benedetto Daniela^[5], Palumbo Angelo Domenico^[2]

^[1]University of Foggia ~ Dipartimento di Scienze Economiche, Matematiche e Statistiche ~ Foggia ~ Italy ^[2]CRA ~ Research Unit for cropping in dry Environments (SCA) ~ Bari ~ Italy ^[3]University of Bari ~ Dipartimento di geologia e geofisica ~ Bari ~ Italy ^[4]University of Foggia ~ Department of Economic, Mathematical and Statistical Science ~ Foggia ~ Italy ^[5]University of Bari "Aldo Moro" ~ Earth science and geo-environmental ~ Bari ~ Italy

Soil water content (SWC) is a critical attribute in Precision Irrigation. Direct measurements are costly and relative sparse, so there is interest in methods to predict SWC at unsampled sites from sampled data. The precision of such predictions can be improved if covariates are incorporated into the predictor. Two efficient ways are: a) linear mixed effect model (LME), in which the spatial processes is obtained by splitting the total variability in a systematic term or mean effect, a spatially correlated component and a random noise, and b) kriging with external drift (KED), a non-stationary geostatistical technique, assuming covariates to have a linear effect on target variable. Geoelectric sensors provide non-invasive information on soil. Their outputs are quite sensitive to SWC, therefore, they can be used as covariates in SWC predictor. The objective of this work was to compare the LME and KED, based on geophysical sensing, to estimate shallow SWC. The surveys were conducted in a south-eastern Italy field, using GPR at two frequencies, 600 and 1600 MHz, EMI and TDR, and 36 soil samples were collected to 20-cm depth for gravimetric SWC measurements. Three LMEs, using three (spheric, exponential and Gaussian) correlation functions were used and compared with KED using a set of cross validation criteria. The mixed models showed a quite similar behaviour even if exponential model outperformed the other two. The covariates used in the mixed models and in KED predictor were different though the results of cross-validation did not show clear differences between the two approaches.

Geophysics is commonly used to predict soil parameters (e.g. soil thickness, soil constituents and properties) over large areas in addition to punctual information given by soil augering. Among the various geophysical tools, the methods based on electrical resistivity measurements give good results providing that the bedrock is homogeneous. However, in the case of heterogeneous bedrock, the resulting data can be misinterpreted, due to inter-relationships between soil resistivity and some soil properties, which may be related to the bedrock lithology. In this study we use electric and electromagnetic methods to (1) map soil thickness over an area with heterogeneous bedrock and (2) assess the relationships between soil resistivity and some constituents of soils (contents in silt, sand, organic carbon and CaCO₃). The study site corresponds to a 100 ha cultivated hillslope located in the SW Parisian Basin (France) and covering 3 types of the Upper Cretaceous sedimentary formations characterised by contrasted resistivity values. The resistivity of the bedrock was measured using an electromagnetic prospection with an EM31 conductivity meter and 44 electrical soundings, whereas soil resistivity was precisely known from an ARP (Automatic Resistivity Profiling) survey at 3 different depths of investigation. Soil thickness was measured at 650 points by manual augering, and soil analyses were performed at 248 points. Geostatistical analyses were tested to assess the relative influence of the different soil properties on the resistivity data for each bedrock type.

CONSTRUCTING A LAYERED ELECTRICAL CONDUCTIVITY MODEL FROM A COMBINATION OF PROXIMAL AND PROBE SENSOR DATA

Piikki Kristin^[1], Söderström Mats^[1], Wetterlind Johanna^[1], Stenberg Bo^[1]

^[1]SLU, Swedish University of Agricultural Sciences ~ Department of Soil and Environment ~ Skara ~ Sweden

Soil apparent electrical conductivity (ECa) can be measured with proximal electromagnetic induction sensors. They are affected by the whole profile and different approaches have been used to extract layered ECa models from the depth-integrated data. One example is to use measurements at multiple heights (1). In the present study, ECa data from a dual-depth proximal sensor (EM38 Mk2 2; Geonics Ltd.) was combined with ECa data from a probe sensor (P4000; Veris technologies Inc.). A similar combination has previously been used for numeric solution of ECa profiles with goal to predict topsoil depth (2). Measurements were made at a 50 hectare field in Sweden. The proximal data (transects 24 m apart) were interpolated to a 10*10 m² grid and the probe data (100 random stratified points) was averaged for three depth intervals (0-20 cm, 40-60 cm and 60-80 cm). Multivariate adaptive regression splines (MARSplines) prediction models were parameterized for each layer using probe ECa as reference data. The two proximal ECa variables and the predicted ECa for any above layer were used as predictors. Twenty probe points omitted from the calibrations were used for validation. The modeling efficiency was 0.73 for the upper layer and 0.79 for the two deep layers. Possible applications are soil type mapping and spatial soil water monitoring in top and sub soil. References 1. Borchers B. et al. 1997. Soil Sci Soc Am J 61, 1004-1009. 2. Sudduth, K. et al. Proceeding for The second global workshop on proximal soil sensing, Montreal, Canada, 2011.

SOIL ELECTRICAL CONDUCTIVITY AND PLANT-AVAILABLE NUTRIENTS – A CASE STUDY

Gebbers Robin^[1], Lück Erika^[2]

^[1]Leibniz-Institute for Agricultural Engineering ~ Engineering for Crop Production ~ Potsdam ~ Germany ^[2]University of Potsdam ~ Earth Sciences ~ Potsdam ~ Germany

Detection of soil variability by mapping apparent soil electrical conductivity (ECa) with geo-electrical methods has become popular in soil science and related disciplines. ECa maps are regularly used to predict soil fertility in terms of soil texture, soil water content, concentration of nutrients, salinity, compaction etc. However, correlations between these target parameters and ECa often vary from field to field. In the case of the important plant-available nutrients (PAN) P, K, and Mg studies reported very different results varying from negative to positive correlations. Thus, the objective of this work was to study the relationship between ECa and some PAN (P, K, and Mg) in more detail. ECa data were obtained with a multi-electrode Wenner array (electrode spacing 0.5 m) over multiple depths. Soil samples were collected at 20 position from three depths (0 – 30 – 60 – 90 cm) and analysed for soil texture, cation exchange capacity (CEC), exchangeable ions (K, Mg, Na, Ca) and PAN (P, K, and Mg). Correlations between ECa, CEC and clay content were positive for all soil layers. However, relationships between ECa, CEC and clay on the one hand and plant-available K and Mg on the other hand were different in the three soil layers. The main reason for this seems to be the higher concentration of exchangeable Ca⁺ in the upper soil layers due to liming which has altered of the composition of cations. While liming regimes may vary from field to field correlations between cationic PAN may vary too.

APPLICATION OF NON-INVASIVE METHODS FOR ASSESSING SOIL COMPACTION WITHIN AGRICULTURAL TRAMLINES

Shanahan Peter^[1], Quinton John^[1], Binley Andrew^[1], James Michael^[1]

^[1]Lancaster University ~ Lancaster Environment Centre ~ Lancaster ~ United Kingdom

Compaction of cultivated soil reduces root penetration, rainwater infiltration, and increases tool draft. Tramline lanes, common features in commercial agriculture, represent localized areas of soil compaction created by heavy farm traffic. Tramlines can also exacerbate runoff and erosion from sloping arable land. The aim of this study is to investigate the impact to soil structure of cultivated soil under tramline wheelings. The objectives are: (1) apply non-invasive means of soil structure analysis to determine the extent of wheeling compaction, and (2) determine the effectiveness of soil compaction mitigation methods in alleviating soil structure compaction. Field trials of non-invasive soil analyses are continuing. We anticipate that the results will improve the accuracy in monitoring soil structure over conventional means of soil analysis. Preliminary results indicate that laboratory soil electrical resistivity measurements on soil cores are sensitive to different levels of compaction. Thus we expect to be able to use field-based electrical imaging techniques as a means of mapping field variation in soil structure. X-ray radiography of core samples provides evidence of bulk density distribution for various treatments, with wheelings significantly increasing soil bulk density to depths of 70 90 mm. Photogrammetry, 3D surface modeling from 2D digital imagery, has been successfully applied in the field to generate digital elevation models of wheeled surfaces allowing for the analysis of soil structure deformation under heavy farm traffic treatments. Results so far indicate reduced deformation under low-ground pressure tyres, with improved accuracy and speed of data acquisition over conventional methods (e.g., pin meters).

Applicability of near infrared reflectance (NIR) spectroscopic technique to integrate the knowledge of soil properties was tested on soils from three different forests in the Cilento and Vallo di Diano National Park (southern Italy). For each forest, 8 samples from the 0-5 cm topsoil layer were analyzed for their reflectance in the wavelength range of 300–2500 nm and for chemical (pH, total organic C, total N, Fe, Mg, Mn, K and Zn available fractions) and biological (microbial and fungal biomass, respiration, FDA hydrolysis and β -glucosidase activity) properties. Biological properties are considered good indicators of soil quality and their interpretation may be supported by optical investigations. In an attempt to extend the current knowledge of Mediterranean forest ecosystems, the present study provides information on different biological, chemical and physical properties of soils from Apennines mountain environments (southern Italy), in holm oak, Turkey oak and beech forests ranging from 400 to 1600 m a.s.l. We observed that most of the investigated parameters were variable, possibly due to the strong differences in parent material, organic matter content and quality, as well as in moisture and thermic regime. The biological properties were correlated with some chemical properties (pH and base saturation), as observed in soils from other types of environment. Altitude and plant cover had a clear effect on the biological and chemical properties. Selected spectroscopic bands were correlated with soil biological activities, making this technique useful for understanding of processes involved in forest soil carbon dynamics.

USING VNIR REFLECTANCE SPECTRA OF DRIED GROUND SOILS TO PREDICT PROPERTIES OF SOILS SCANNED MOIST AND INTACT OF SOILS SCANNED MOIST AND INTACT

Morgan Cristine^{*[1]}, Thomasson Alex^[2], Ge Yufeng^[2]

^[1]Texas A&M University ~ Soil& Crop Sciences ~ College Station ~ United States ^[2]Texas A&M University ~ Biological and Agricultural Engineering ~ College Station ~ United States

VNIR spectroscopy is a useful tool for rapid measurement of many soil properties, and it can be used proximally. In proximal sensing, soil is scanned intact, either on a core pulled from the soil or in situ with a probe that penetrates the soil. In either case, soil is scanned under the current moisture conditions. The use of VNIR spectral libraries generated from dried and ground soils to predict soil properties thus presents a problem. To address this challenge, we applied an external parameter orthogonalization (EPO) algorithm to remove the effect of soil moisture and other effects associated with scans of intact soil samples. For data, we used a library of approximately 250 soil spectra recorded under three different soil conditions: field-moist and intact, air-dried and intact, dried and ground. The EPO algorithm was found to be a promising method for removing uncertainties that arise in the application of proximal VNIR spectroscopy of natural soil.

S04.01b -4

COMPARISON OF NEAR- AND MID-INFRARED SPECTRA TO PREDICT SOIL ORGANIC CARBON AND TOTAL NITROGEN

Madhavan Dinesh Babu^[1], Jangammanaidu Krishnaraj Saravanan^[1], Mendham Daniel^[2], Kitching Matt^[3], Weston Chris^[1], Baker Tom^[1]

^[1]The University of Melbourne ~ Forest and Ecosystem Science ~ Melbourne ~ Australia ^[2]Commonwealth Scientific and Industrial Research Organisation ~ Sustainable Ecosystems ~ Hobart ~ Australia ^[3]Department of Primary Industries, Victoria ~ Future Farming Systems Research ~ Melbourne ~ Australia

Near-infrared (NIR) and mid-infrared (MIR) spectroscopy combined with partial least squares regression (PLSR) have been demonstrated as an alternative technique to estimate soil organic carbon (SOC) and total nitrogen (TN). The objective of this study was to evaluate the performance of calibration models developed in soils under land-use changes from NIR and MIR spectral ranges to predict SOC and TN. Soils from a broad range of climate and soil types were collected from 31 paired sites of *Eucalyptus globulus* plantation and adjacent pastures in south-western Australia. Soil samples were scanned from 8000-4000 cm⁻¹ (1250-2500 nm) for NIR spectra and 4000-400 cm⁻¹ (2500-25000 nm) for MIR spectra. The SOC and TN concentrations were determined using dry combustion. A total of 184 soil samples (23 sites) were used to develop the PLSR calibration models, whereas 64 independent samples (8 sites) formed the validation set. The calibration models of NIR spectra were statistically sound, but the validation predictions were poorer [SOC ($R^2_{cal} = 0.90$, $R^2_{val} = 0.54$, RMSEP = 1.13 and Bias = 0.56), TN ($R^2_{cal} = 0.93$, $R^2_{val} = 0.60$, RMSEP = 0.32 and Bias = 0.17)], when compared to robust calibrations and validation predictions of MIR spectra [SOC ($R^2_{cal} = 0.96$, $R^2_{val} = 0.94$, RMSEP = 0.40 and Bias = 0.08), TN ($R^2_{cal} = 0.94$ and $R^2_{val} = 0.93$, RMSEP = 0.13 and Bias = 0.06)]. The MIR spectroscopy was found suitable for precise SOC and TN predictions; however larger sample populations with relevant spectral pre-treatments can improve NIR spectral predictions.

S04.01b -5

LANDSCAPE SCALE DIGITAL SOIL MAPPING USING FIELD SCALE GEOPHYSICAL SENSING DATA

Schmidt Karsten^{*[1]}, Behrens Thorsten^[1], Werban Ulrike^[2], Scholten Thomas^[1]

^[1]University of Tuebingen ~ Department of Geosciences ~ Tuebingen ~ Germany ^[2]UFZ – Helmholtz Centre for Environmental Research ~ Department of Monitoring and Exploration Technologies ~ Leipzig ~ Germany

This talk presents and compares multiple new approaches to landscape scale digital soil mapping using field scale geophysical sensing data (EM and Gamma). The idea is to validate how such data can be used most efficiently to support landscape scale soil texture predictions. All concepts were compared in a low relief area in northern Germany using hyperscale digital terrain analysis as the only predictor. The approaches tested are: a) The Benchmark: no geophysical data used / landscape scale hyper-scale terrain features only b) Using field scale soil calibration model on geophysical data, which has been extrapolated to the landscape. c) Using field scale geophysical calibration model to extend the field scale soil data pool. d) Using extrapolated geophysical data as additional predictors at the landscape scale. e) Using geophysics to extend the field scale soil data pool and using extrapolated geophysical data as additional predictors. Eighty soil samples at two depth intervals were derived to cover the feature space of the geophysical sensor data and for calibrating the soil property models. Validation is based on 20 fully independent soil samples outside the sampling areas to cover the geographical space. Validation shows that modelling approaches a and b perform worst resulting in $R^2 = 0.53$. Modelling approaches c – e show accuracies of up to $R^2 = 0.63$ (e). This significant increase clearly demonstrates the high potential of including field scale geophysical data for landscape scale digital soil mapping to meet the global growing demand of high-resolution soil data.

S04.01b -6

THE OPTIMAL CALIBRATION SET SIZE AND THE SAMPLING STRATEGY FOR MODELING SOIL VIS-NIR SPECTRA AT THE FIELD SCALE

Ramirez-Lopez Leonardo^[1], Demattê Jose^[2], Schmidt Karsten^[3], Behrens Thorsten^[3], Scholten Thomas^[3]

^[1]Université Catholique de Louvain / University of Tübingen ~ Georges Lemaître Centre for Earth and Climate Research, Earth and Life Institute / Institute of Geography, Physical Geography, University of Tübingen ~ Louvain-la-Neuve ~ Belgium ^[2]University of Sao Paulo ~ Soil Science ~ Piracicaba ~ Brazil ^[3]University of Tuebingen ~ Institute of Geography, Physical Geography ~ Tuebingen ~ Germany

Soil routine analyses are very expensive and time consuming. These issues represent key disadvantages for high resolution soil mapping at field scale. Quantification of soil attributes based on vis-NIR spectroscopy is rapid, accurate and more economic than conventional methods. By using a small (but representative) number of soil samples from a given area is possible to calibrate vis-NIR models of soil attributes and then those models to predict soil attributes efficiently in a large number of soil samples belonging to that area. Despite the well known potential of vis-NIR spectroscopy in soil attribute mapping, research on the adequate size of the calibration set has not received enough attention. In this work we investigated the effect of the calibration sampling strategy on the optimal calibration set size (oCSS). We compared three calibration sampling algorithms: Kennard-Stone (KS), fuzzy k-means (FKM) and conditioned latin hypercube (cLHS). These algorithms were used to identify the oCSS for clay content (CC) and exchangeable calcium (Ca++) using Support Vector Regressions (SVR). We collected 1000 samples at two depths in an area of 500 hectares located in Brazil. We concluded that the oCSS is largely affected by the calibration sampling strategy. Our results also suggest that in the context of proximal soil sensing an effective sampling strategy is very important especially when a small number of calibration samples are used.

OPTIMALISATION OF PASSIVE GAMMARAY SOIL SURVEYS

Loonstra Eddie*^[1]

^[1]The Soil Company ~ ~ Groningen ~ Netherlands

Soil, as most substances on earth, is radioactive by nature. The activity concentration of radionuclides in soil can be measured with mobile passive gamma-ray soil sensor systems. This is a complex process in which several factors are of importance in order to retrieve qualitative data with low uncertainty. Basically caused by the fact that radioactive decay from the source "soil" is unpredictable and random, making mobile surveys harder. Optimisation of mobile passive gamma-ray surveys requires a balance of detector design, data processing and field operations. The scintillating material and its size are critical design parameters for the interaction with gamma-rays. The optimum efficiency will be obtained for a large detector volume with high density and high Z-values. The quality of the electronic components as photomultiplier, multichannel analyser and amplifier are relevant as well. The processing of the measured gamma-ray spectrum has to deal with stabilisation due to temperature drift and –more generic- calibration of the detector. Several denoising methods exist to overcome uncertainty caused by external factors as survey speed, detector height, water & rock content in soil. The statistical approach used to estimate soil property maps determines the method of data processing and analysis. The spectrum analysis approach also affects the uncertainty of the outcome. Side effects of external sources such as cosmic radiation can be overcome by calibrating the detector. However, for the negative effects of rainfall or nonsoil objects that consist of minerals on a survey no corrective solution are available. These circumstances simply must be avoided.

REPEATED GAMMA-RAY MEASUREMENTS USING A MOBILE DEVICE ON A RIVER FLOOD PLAIN AREA

Dierke Claudia*^[1], Werban Ulrike^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Monitoring and Exploration Technologies ~ Leipzig ~ Germany

In the past, gamma-ray measurements have been used for geological surveys and deposit exploration using airborne and borehole logging systems. For these applications, the relationships between the measured physical parameter – the concentration of natural gamma emitters ⁴⁰K, ²³⁸U and ²³²Th – and geological origin or sedimentary developments are well described. Based on these applications and knowledge in combination with adjusted sensor systems, gamma-ray measurements are used to derive soil parameters to create detailed soil maps e.g., in digital soil mapping (DSM) and monitoring of soils. Therefore, not only qualitative but also quantitative comparability is necessary. Grain size distribution, type of clay minerals and organic matter content are soil parameters which directly influence the gamma-ray emitter concentration. The concentration is influenced by endogenous processes like soil moisture variation, erosion and deposition of material or cultivation. A time series of gamma-ray measurements was used to observe changes in gamma-ray concentration on a floodplain area in Central Germany. The study area is characterised by high variations in grain size distribution and occurrence of flooding events. For the survey, we used a 4l NaI(Tl) detector with GPS connection mounted on a sledge, which is towed across the field sites by a four-wheel-vehicle. The comparison of data from different dates shows similar structures with small variation between the data ranges and shape of structures. We will present our experiences concerning the measurement under variable field conditions and their impacts on gamma-ray data quality.

UNDERSTANDING THE GAMMA-RAY SIGNAL OF SOILS - TOWARDS A QUANTITATIVE UNDERSTANDING OF FACTORS, PROCESSES AND PROPERTIES

Herrmann Ludger^[1], Schuler Ulrich^[2], Erbe Petra^[1], Baritz Rainer^[2], Stahr Karl^[1]

^[1]Institute of Soil Science and Land Evaluation ~ University of Hohenheim (310) ~ Stuttgart ~ Germany ^[2]Federal Institute for Geosciences and Natural Resources (BGR) ~ B2.2 Spatial Information Soil and Water ~ Hannover ~ Germany

Gamma-ray spectrometry is an underestimated technique for soil mapping though it has a higher potential than other ones, since it can deliver information on soil forming factors (parent rock), processes (erosion, clay illuviation) and properties (i.e. texture) and can be applied via proximal as well as remote sensing at the same time. One major reason for its limited application is that so far statistical correlation with properties was applied rather than quantitative understanding of the signal searched for. The paper reviews the dominant factors and processes influencing the gamma-ray signature based on case studies in Thailand and Germany and presents applications for WRB soil reference group, erosion and soil property mapping.

**TESTING THE IDENTIFICATION OF GENETIC HORIZONS IN POLISH SOILS WITH THE
DIFFUSE REFLECTANCE SPECTROSCOPY**

Kazmierowski Cezary^[1], Kusneirek Krzysztof^{*[1]}

^[1]Adam Mickiewicz University ~ Department of Soil Science and Remote Sensing of Soils ~ Poznan ~ Poland

A proper description of a soil profile requires an expert knowledge about genetic horizons, but often the soil reconnaissance, analysis and sampling in the field is conducted by inexperienced soil scientists or farmers. The aim of this work is to test how the information brought by the laboratory diffuse reflectance spectroscopy of the air-dried and sieved samples correlates with the actual classification of soil horizons and profiles as well as with some qualitative soil properties. This analysis shows to what extent it is possible to be verify the identification of a given soil horizon sample by an automated analysis. Samples from a variety of soil types, collected in several sampling campaigns across various landscapes of Poland, were taken into consideration, including (according to the WRB): Albeluvisols, Arenosols, Cambisols, Chernozems, Fluvisols, Gleysols, Luvisols, Phaeozems, Regosols, an Rendzic Leptosols. This dataset of soils incorporated several surface and subsurface horizons such as: albic, argic, calcic, cambic, histic, melanic, mollic, to name few. Several methods were used in this study for extracting the spectral information from Vis-NIR spectra measured in the laboratory conditions by ASD FieldSpec3 spectrometer. Apart from using multivariate factorial and clustering methods, widely adopted in soil spectroscopy, also simple analyses of the shape of the spectra using mathematical transformations and indices were conducted.

DETECTION OF ANCIENT ACTIVE CHANNEL ZONES USING HYDROGEOPHYSICAL METHODS: AN APPROACH FOR MORE EFFECTIVE CHANNEL RESTORATION

Altdorff Daniel^{*[1]}, Dietrich Peter^[1], Epting Jannis^[2], Huggenberger Peter^[2]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Department Monitoring and Exploration Technologies ~ Leipzig ~ Germany ^[2]Applied and Environmental Geology University of Basel ~ Department of Environmental Sciences ~ Basel ~ Switzerland

River restoration and applied restoration measures are of increasing importance for integrated water resources management as well as for ecosystem services. However, often river restoration is planned and realized by engineering and constructing aspects only and hydrogeological settings and ancient active channel (ACC) are neglected. As a result desired outcomes of restoration projects are reduced with no significant alteration of stream conditions. An opportunity to reach the full restoration potential is to investigate ancient active stream courses by applying hydrogeophysical. In this study, we investigate the ACC zone in a floodplain of a modified low-mountain river in Switzerland by means of hydrogeophysical data with two different approaches. In the first approach we generate iteratively by means of various electric conductivity (EC) forward models a 3D geological structure model (GSM) for delineation of potential ACC. Thereby we vary the geological input parameters based on the measured data until the synthetic EC maps fit to the real EC values. Subsequently we use the best fitted input data for generation of final GSM. In a second approach we generate a K-means cluster map for the floodplain surface that combines the main characteristics from multilayered subsurface data. The obtained cluster delineates parts of significant different soil conditions and provides therewith an indication for areas above potential ACC. Hence the map distinct between areas of higher and lower flood vulnerability as well as higher and lower possible river affection. A comparison with independent Ground Penetrating Radar data has confirmed the obtained structures of both results.

A RAPID, PORTABLE METHOD FOR ACQUIRING TERRAIN MODELS OF SOIL SURFACES

James Mike R^[1], Rodriguez Gonzalez Jesus^[2], Quinton John^{*[1]}, Gomez Jose A^[2]

^[1]Lancaster University ~ Lancaster Environment Centre ~ Lancaster ~ United Kingdom ^[2]Universidad de Córdoba (UCO) ~ Instituto de Agricultura Sostenible (IAS-CSIC) ~ Córdoba ~ Spain

In this paper we demonstrate developments in computer vision technology that now offer soil scientists a new option for acquiring high precision, high accuracy topographic information across a range of scales, using freely available software and little more than a consumer-grade digital camera. The technique is based on collecting multiple photographs of a scene from different positions, but without the relatively strict image acquisition and control point requirements of traditional photogrammetry. Automated 'reconstruction pipeline' software (that can be downloaded from the internet, e.g. <http://www.visual-experiments.com/demos/sfmtoolkit/>) then uses a combined structure-from-motion and multi-view stereo approach (SfM-MVS) to generate dense point clouds of millions of points. For accuracy, and to allow error analysis, additional software (http://www.lancs.ac.uk/staff/jamesm/software/sfm_georef.htm) has been developed to permit georeferencing using observations made within the image set, rather than requiring feature matching within the point cloud. Here, we demonstrate the reconstruction technique on agricultural field sites that have undergone different surface treatments with a roller, chisel plough and mouldboard plough. The SfM-MVS technique produced point clouds with a density of ~50 points cm⁻² were generated, from which DEMs with grid intervals of 5 mm were produced. The DEMs showed RMS residuals of <5.6 mm when compared with data acquired by an in-house laser-based system. A lack of systematic error suggests that SfM-MVS techniques could offer a viable low-cost alternative to laser-based measurement techniques at this (and other) spatial scales, with additional advantages of reduced acquisition time and portability.

**IMPROVING THE SATELLITE-BASED CHARACTERIZATION OF RANGELAND DEGRADATION
BY AN ADVANCED MULTIPLE ENDMEMBER SPECTRAL UNMIXING APPROACH**

Hill Joachim*^[1]

^[1]University of Trier ~ Environmental Remote Sensing & Geoinformatics ~ Trier ~ Germany

Land degradation in semi-arid and sub-humid rangelands is usually dominated by processes of soil degradation/erosion and the associated loss of biotic productivity, tightly coupled through characteristic feedback loops. The use of optical remote sensing systems for monitoring and characterizing such interconnected processes over time requires efficient analytical tools for decoupling the spectral effects of changing soil and vegetation conditions. Since regular (multi-annual) observation strategies will unavoidably be affected by phenological variations it is especially important not only to assess the photosynthetic but the total (i.e. green and dry) biomass changes in comparison to soil characteristics. Standard vegetation indices are not useful for solving this task as they are sensitive to subtle variations of green biomass but largely disturbed by soil and dry vegetation signal components. Spectral mixture analysis (SMA) provides a more efficient interpretative framework. However, SMA is prone to numerical problems and decreasing accuracies in case that spectrally similar endmembers must be considered simultaneously. This study demonstrates how these limitations can be overcome through a computationally efficient strategy for using multiple spectral endmember configurations. The algorithm is validated against spectra of known biophysical characteristics and different soil backgrounds which are simulated through a geometric optics leaf-canopy reflectance model (Prospect-5 - 4SAIL - FLIM). Its application to real satellite observations (Landsat-TM/ETM+ and MODIS) is demonstrated in the context of a study on long-term rangeland degradation in Inner Mongolia (China) initiated within the DeSurvey Project (EU FP6).

TOWARDS NOVEL APPROACHES FOR COMPILING REMOTE SENSING

Cherlet Michael^[1], Ivits Eva^[1], Sommer Stefan^[1], Mehl Wolfgang^[1]

^[1]European Commission ~ DG Joint Research Centre ~ Ispra ~ Italy

A new World Atlas on Desertification (WAD) is being compiled under joint coordination of the ECJRC and UNEP. The need for baseline information on the status of desertification and land degradation, along with agreed methodologies has to be addressed urgently. At global scales, information on vegetation/land cover dynamics is a core component to assess the state of desertification and land degradation resulting from a combination of natural/environmental and human/socio-economic drivers. Many studies use Vegetation Indices (VI) as base layer and we enhance this information by calculating phenological metrics from the VI time series to derive further insight on vegetation cover functioning and related land use. In this study, we objectively select phenological metrics best adapted to specific human-ecological systems through an adapted stratification. Their combined variation is analysed related to compositional changes e.g. land use changes, and against inter-annual meteorological fluctuation within the stratification. We rely on a scheme of convergence of evidence of trend and change from combinations of the metrics that are interpreted as descriptors of the dynamics and fluctuation of the Human-Environment system. Derived baseline products describe the status and productive capacity of vegetation/land cover during a reference time period, reflecting the regime of inter-annual fluctuation, together with a likely tendency to maintain the current functional level for the provision of the related ecosystem service. Results are compared to land degradation assessments for selected areas.

INTEGRATING ENVIRONMENTAL INFORMATION IN GULLY INITIATION TOPOGRAPHIC THRESHOLDS : APPLICATION TO THREE REGIONS OF WALLONIA (BELGIUM)

Maugnard Alexandre^{*[1]}, Charles Bielders^[1], Senne Van Dyck^[1], H  l  ne Cordonnier^[2], Abdel Ilah Mokadem^[2]

^[1]Universit   catholique de Louvain ~ Earth and Life Institute ~ Louvain-la-Neuve ~ Belgium ^[2]Service Public de Wallonie ~ Direction G  n  rale Op  rationnelle de l'Agriculture, des Ressources Naturelles et de l'Environnement ~ Namur ~ Belgium

Gully erosion is responsible for 20% to 80% of the total soil erosion by water in Belgium and causes serious damages. In order to explain and predict the initiation of gully erosion, many studies have focused on topographic thresholds which depend on the contributing area and slope at the gully head. However, this approach does not integrate specific environmental information such as soil type and land use. Furthermore, several methods exist to determine the threshold. This study proposes a simple methodology to integrate soil and land use information in the topographic thresholds and compares the two main approaches used for drawing gully initiation thresholds. This methodology is applied to 3 agro-pedological regions of Wallonia (Belgium). For each region, a gully database was created by digitizing gullies on the basis of aerial photographs. Slopes and contributing areas at the gully heads as well as land use and soil type in the contributing areas were extracted. Using this information, runoff volumes were calculated using the SCS Curve Number method. Gully initiation thresholds defined using slope and runoff volume are compared with thresholds based on slope and contributing area. The former approach is better able to discriminate among contributing areas that have heterogeneous land uses and soil types. We found that regional differences in topographic and environmental conditions lead to differences in the thresholds. These differences are dependent on the type of thresholding method used. . The observed differences are sensitive to the method used for drawing the threshold.

S04.02a -4

ESTIMATING RAINFALL EROSIVITY FOR AFRICA WITH TRMM DATA

Vrieling Anton*^[1], Sterk Geert^[2], De Jong Steven M.^[2]

^[1]University of Twente ~ Faculty of Geo-Information Science and Earth Observation ~ Enschede ~ Netherlands ^[2]Utrecht University ~ Department of Physical Geography ~ Utrecht ~ Netherlands

Rainfall erosivity is a measure for the erosive force of rainfall. Rainfall kinetic energy determines the erosivity and is in turn greatly dependent on rainfall intensity. Attempts for its large-scale mapping are rare. Most are based on interpolation of erosivity values derived from rain gauge data. For data-poor regions this is not an option. This study examines whether erosivity can be accurately mapped for Africa using 3-hourly TRMM Multi-satellite Precipitation Analysis (TMPA) precipitation data. Using intensity-erosivity relationships and 11 years of TMPA data (1998-2008) we calculated average annual erosivity. We also calculated erosivity from the monthly TMPA data product using the often-applied Fournier and modified Fournier indices. From literature 39 locations with long-term erosivity values were retrieved. Comparison showed that the modified Fournier index attains a much stronger correlation ($r=0.84$) than the results based on 3-hourly data ($r=0.71$). We conclude that 1) the 3-hourly and 0.25-degree TMPA data provide insufficient detail to represent high intensity erosive events, and 2) monthly satellite-based precipitation provides good spatial estimates of average annual erosivity. Furthermore we discuss how satellite assessments of rainfall erosivity could be used in the future for improved monitoring of soil erosion.

S04.02a -5

SPECTRAL MAPPING OF MEDITERRANEAN SOIL SURFACE CRUSTS

De Jong Steven^{*[1]}, Elisabeth Addink^[1], Rens Van Beek^[1]

^[1]Utrecht University ~ Geosciences ~ Utrecht ~ Netherlands

Soil surface crusts frequently occur in Mediterranean areas. They form on bare soil subject to high-intensity rainfall, resulting in a hard, impenetrable layer that impedes infiltration and hampers the germination and establishment of plants. The adverse consequences of overland flow and reduced fertility can lead to erosion and ongoing degradation. Therefore, information on the distribution of surface crusts is essential to combat the undesired effects. In a study area in southern France we compared the physical and hydrological properties of crusts and underlying soil, we identified spectral characteristics (400-2500 nm) of the crusted and non-crusted soil surfaces using high-resolution field spectra, and we investigated the potential of mapping crust occurrence using airborne, hyperspectral images. Crusting markedly reduces the infiltration capacity and crust strength varies between soil types. Spectral differences are small, mainly in albedo values and in absorption band depth and shape. Differences in absorption band features in the spectra of crusts and noncrusted surfaces are small. Spectral feature fitting and linear spectral unmixing algorithms were applied to airborne images to evaluate the possibilities of mapping surface crusts. Crusts could be mapped in fallow, agricultural fields, but the spectral response of natural badlands was too fragmented for crust mapping.

Rapid identification and large-scale mapping of salt-affected soils will help improve salinity management in watersheds and ecosystems. Remote sensing data for the reason of broad and integrated view, better capability for calibration and multi spectral and temporal data are useful tools for identifying salt. Salts tends to concentrate on the soil surface in dry and irrigated areas. As salinity increases, more salts will appear at the soil surface, favoring the use of conventional remote sensing tools. Potentiality of various sensors is important in detecting saline soils and salt crusts. Therefore, in this study we evaluated the data of ASTER and LISS III sensors in Playas of DAMGHAN, KASHAN and MAHARLOO regions, IRAN. The first, the imageries corrected and then we used principal component analysis, normalize difference vegetation index and band rationing in detecting of saline soils. In the band rationing method, two indices were applied, normalized difference salt crust index (NDSCI) and ratio salt crust index (RSCI). Investigation of feature space graphs in saline and non-saline soils indicated that NDSCI and RSCI had the best separability. Then, the maps of these soils prepared. In these maps, saline soils with salt crusts were perfectly clear. In applied approaches showed, band rationing and using of these two indexes (NDSIC and RSCI) were very efficient.

The SOFIA project (ESA AO-6280), supported by the Province of Bolzano in the framework of the IRKIS project, aimed at investigating the effectiveness of new generation SAR imagery for the estimation of topsoil moisture content in mountain environments. In this paper we present the main results of the activity carried out in this framework. A set of 30 fully polarimetric RADARSAT2 SAR images acquired over the Alto Adige area (Northern Italy) during the summer 2010 and 2011 has been analyzed. The data have been processed using an advanced retrieval algorithm based on the Support Vector regression method and ancillary data for obtaining spatially and temporally distributed maps of soil moisture content over alpine pasture and meadows. The output maps have been compared with ground measurements of soil moisture content at different depths as well as precipitation data from meteorological stations. The aim was to assess the effectiveness of the SAR data and the proposed algorithm to derive robust and accurate information on the topsoil moisture status in alpine areas. The achieved results are promising and suggest the effectiveness of the proposed retrieval system in following both the spatial and temporal patterns of the variable of interest. A main limitation encountered is the reduced swath of RADARSAT 2 polarimetric SAR imagery. This prevents the possibility to acquire multiple scenes over the same area with different geometries, in order to minimize the effects of geometric distortions that are common in SAR imagery of mountain areas where the sideslopes have different orientations.

^[1]GFZ German Research Center for Geosciences ~ Section 1.4 Remote sensing ~ Potsdam ~ Germany ^[2]Berlin University of Technology ~ Computer Vision and Remote Sensing ~ Berlin ~ Germany ^[3]Tel Aviv University ~ The Department of Geography and the Human Environment ~ Tel Aviv ~ Israel ^[4]DLR German Aerospace Center ~ German Remote Sensing Data Center, Applied Spectroscopy workgroup ~ Wessling ~ Germany

Can we develop automatic algorithms for soil mapping based on spectral reflectance? This question comes nowadays at a high relevance level with the upcoming launch of the next generation of hyperspectral satellites (EnMap, Hyper-X, HypSIrI, HypXIM) and the increasing demand for the availability/accessibility of hyperspectral soil products from the geoscience community. The availability of automatic toolboxes will be a major step toward the operational use of soil hyperspectral products for Earth's surface processes monitoring and modelling, allowing non-experienced users to access new information with non-expensive software packages where repeatability of the results is an important prerequisite. In the frame of the EU-FP7 EUFAR (European Facility for Airborne Research) project and EnMap science program, higher performing soil algorithms were developed as demonstrators for end-to-end processing chains with harmonized quality measures. For this, the HYSOMA (Hyperspectral SOil MAPper) software interface was developed at the GFZ German Research Center for Geosciences. It focuses on the fully automatic generation of semi-quantitative soil maps for key soil parameters such as soil moisture, soil organic carbon, soil minerals (iron oxides, clay minerals, carbonates). The validation of the HYSOMA soil products based on ground truth data showed correlations from R² of 0.6 (clay) up to >0.9 (moisture). The HYSOMA is IDL-based and distributed for free under the idl-virtual machine. It is integrated in DLR hyperspectral processing chain, and (in process) in EUFAR Toolbox. In this presentation, we will show the HYSOMA interface, methods used, and case studies demonstrating the capabilities of the software.

ESTIMATING FIELD SCALE SOIL TEXTURAL PROPERTIES FROM AIRBORNE AND SATELLITE IMAGING SPECTROSCOPY

Casa Raffaele^{*[3]}, Castaldi Fabio^[3], Pascucci Simone^[2], Palombo Angelo^[2], Pignatti Stefano^[2]

^[1]University of Tuscia ~ Dipartimento di Scienze e Tecnologie per l'Agricoltura, le Foreste, la Natura e l'Energia (DAFNE) ~ Viterbo ~ Italy ^[2]Consiglio Nazionale delle Ricerche ~ IMAA ~ Potenza ~ Italy ^[3]University of Tuscia ~ DAFNE ~ Viterbo ~ Italy

Imaging spectroscopy of bare soils has been shown to have considerable potential for the estimation of properties such as soil texture, determined by clay, silt and sand fractions. Such information would allow the improvement of agronomic management, on the basis of rapid and cost-effective assessment of soil spatial variability. In the present study, images were acquired, by airborne MIVIS (430 – 1270 nm) and space-borne CHRIS-PROBA (415 – 1050 nm) sensors, over bare soil fields in Maccarese, Central Italy, at different dates in 2010 and 2011. Concurrently, extensive soil sampling was carried out for lab determination of soil particle size fractions. Soil analysis data were used to derive maps of measured clay, silt and sand, by means of kriging. Soil data were linked to the spectral signature of corresponding CHRIS or MIVIS pixels. Spectra, corrected and pre-treated, were used to calibrate prediction models for the estimation of clay, silt and sand, through partial least-square regression (PLSR). The performance of the predictions was subsequently evaluated by employing an independent dataset, acquired over an adjacent field. Accuracy of predictions was assessed from several statistics, such as bias, root mean square error of prediction and ratio of standard error of prediction to sample standard deviation (RPD). The results revealed the importance of the conditions in which the images were acquired, such as the pattern of soil moisture. This aspect explained why, despite a more limited spectral range and a lower spatial resolution of CHRIS as compared to MIVIS, better predictions were obtained.

MAPPING VINEYARD TOPSOIL USING VERY HIGH SPATIAL RESOLUTION IMAGERY IN BURGUNDY, FRANCE

Chevigny Emmanuel^[1], Amélie Quiquerez^[1], Christophe Petit^[3], Pierre Curmi^[4]

^[1]UMR CNRS 5594 ARTeHIS ~ Université de Bourgogne ~ Dijon ~ France ^[2]UMR CNRS LGL-TPE 5276 ~ Université Claude Bernard ~ Lyon ~ France ^[3]UMR 7041 ArScAn ~ Université Paris 1 ~ Paris ~ France ^[4]UMR CNRS Agroécologie Dijon ~ Université de Bourgogne, AGROSUP, INRA ~ Dijon ~ France

Vineyards are known to undergo substantial soil loss in comparison with other types of agricultural land. In this context, local observation of soil loss highlights a high degree of spatial heterogeneity resulting from intra-plot topsoil variability. Studying the relationship between soils and their degradation is therefore crucial in this situation where soil sustainability is threatened. We developed a method based on very high spatial resolution (VHSR) image analysis into visible domain to map vineyard topsoil in Burgundy (France). Aerial images were acquired by the unmanned helicopter Drelia at a 2 cm spatial resolution. After pre-processing images (georeferencing, mosaicing...), we applied principal components analysis to identify several soil surface characteristic classes SSC on images mosaic. Soil surface mapping obtained from images analyze was combined with soil surface descriptions and soil profiles to define soil types by physical and chemical characteristics. Soil sampling was done according the spatial distribution of SSC. For each class, random samples were collected to identify physical (stoniness, soil color, grain-size distribution and clay mineralogy) and chemical (organic matter, nitrogen, iron and total carbonate contents) parameters that characterized soil types in these vineyard hillslopes. By allowing soil surface states to be mapped with a centimeter resolution, this approach provides novel insights and possibilities for documenting soil patterns and for exploring and predicting soil evolution through space and time on hillslopes.

SOIL HYDRAULIC PROPERTIES FROM LOCAL TO REGIONAL SCALE USING REMOTE SENSING AND PHYSICS-BASED MODEL

Mohanty Binayak*^[1]

^[1]Texas A&M University ~ Biological and Agricultural Engineering ~ College Station ~ United States

Ensemble hydrologic fluxes (including evapotranspiration, infiltration, shallow ground water recharge) within and across the vadose zone reflect the evolution of soil moisture at a particular spatial scale (field, watershed, or region) and can be “effectively” represented by one or more linear/nonlinear hydrologic scale parameters. Overarching the above concepts, we hypothesized that effective soil hydraulic property in the root zone at the footprint-scale is an effective indicator for combined soil, topography, and vegetation heterogeneities in land-atmosphere interaction models at different spatial scales. To test this overarching scientific hypothesis we utilize state-of-the-art remotely sensed (RS) soil moisture data at multiple resolutions with a newly developed inverse model including a soil-water-atmosphere-plant model and advanced parameter estimation techniques. Effective root zone soil hydraulic parameters estimated using deterministic or stochastic inverse modeling approach (top-down) will be tested and compared for relative performance against numerical-cum-measurement upscaling schemes (bottom-up) for steady and transient conditions inclusive of various soil textures and structures, small and large scale topographic features, and a range of land covers and root distributions. Predictive watershed scale modeling will test our hypothesis that “effective” hydraulic properties with larger RS footprint-scale measurement support are better predictors than “upscaled” hydraulic properties using local-scale measurements and scaling rules, based on estimated hydrologic fluxes (runoff/stream flow, ET, and soil moisture) and their uncertainties.

QUANTITATIVE RESULTS FROM A NOVEL APPROACH TO REMOTE SENSING OF SOIL MOISTURE CONTENT IN A MICRO PROFILE SECTION UNDER VARIOUS PRECIPITATION ENERGIES

Eliran Alon^{*[1]}, Goldshleger Naftaly^[2], Yahalom Asher^[3], Ben-Dor Eyal^[4], Agassi Menachem^[2]

^[1]Tel Aviv University ~ Porter School of Environmental Studies ~ Tel Aviv ~ Israel ^[2]Ministry of Agriculture and Rural Development ~ Soil Erosion Research Station ~ Rupin ~ Israel ^[3]Ariel University Center ~ Electrical and Electronics Engineering ~ Ariel ~ Israel ^[4]Tel Aviv University ~ Geography and Human Environment, Remote Sensing Laboratory ~ Tel Aviv ~ Israel

We present a first low-cost measurement of the micro-profile of soil moisture-content in the upper root zone. The method is based on millimetre waves, providing improved resolution of the sub-surface concurrent with surface mapping. Development and use of the tools described herein will make it easier to understand processes governing the soil-water interface, such as crust. Point-by-point soil sampling within a field is time-consuming and expensive. Hyperspectral remote sensing in the VIS-NIR-SWIR range (0.4-2.5 μm) is only capable of surface sensing. Ground-penetrating radar (GPR), operating in the range 10 MHz to 5 GHz, penetrates loess soil, for example, to a depth of up to 30 m; however, its resolution at root zone tends to be limited to about 5 to 10 cm. Millimetre waves offer resolution on the order of millimetres and penetration depths on the order of centimetres, thus providing the optimal trade-off between the two parameters. Backscattering of millimetre waves from two soils with different levels of moisture content was measured at 94 GHz. The results show soil-moisture content to be correlated with the standard deviation of the angular variation of the backscattering coefficient of millimetre-wave radiation. The detection depth can be extended with the use of higher incident power from 10 cm currently to include the entire root zone. In the horizontal dimension, the addition of the millimetre-wave technique to existing ones should enable focusing on small regions of interest on the order of 1 m².

Soils are structurally highly heterogeneous systems down to submicron scales. Although processes as the formation of soil interfaces and aggregates which are relevant for the sorption of organic matter are well characterized for the bulk soil, an adequate technique to analyse them in-situ at relevant scale is required. We discuss the state of the art NanoSIMS technology employed at TU München to characterize soil micro-scale interfaces in intact soil aggregates. The NanoSIMS 50L instrument providing a high lateral resolution enables us to study elemental / isotopic distributions at submicron ranges in soil samples. The aim of the present study was to track the fate of fresh OM in intact soil aggregates. Aggregates from a labelling experiment with litter enriched in ¹⁵N were analyzed. The soil material sampled in spring was derived from a cropland (Cambisol) topsoil in Southern Germany on which mustard litter enriched in ¹⁵N was added in fall. The results illustrate that the ¹⁵N-labelled organic matter can be located in micron sized hot spots within the intact soil aggregates. In contrast to first assumptions the ¹⁵N was tracked in mineral rich spheres and not in particulate OM within the soil aggregate. Our data demonstrate that NanoSIMS is a promising tool to visualize soil features which determine specific soil processes at until now unresolved spatial scale.

Soils as heterogeneous systems possess a broad range of functions in the environment, most of them related to water content and fluxes. Among the non-invasive techniques, nuclear magnetic resonance (NMR) methods are particularly convenient since they probe directly the substance of interest: Water. Besides spectroscopy, NMR can be applied in soils as relaxometry, where information about the local dynamics of water in pores is obtained allowing further conclusions about pore sizes and connectivities[1], or as imaging which resolves these parameters spatially. Here we present NMR results obtained with two modified NMR setups. First, the common rf-coil for volume excitation is replaced by a microcoil which probes an area of about 1 mm² and is inserted directly into natural soil material placed in a Halbach magnet. Using relaxometry methods local water content and dynamics can now be monitored locally. The second setup uses a contact-free sensor, the NMR-MOUSE [2], which probes moisture profiles beyond its surface in 200 µm thick slices down to a depth of 2.5 cm. This set-up is extended by a micro-gradient system which additionally allows to obtain high resolution 2D images from the selected slices. The aim is to investigate the interface between soil and roots: the rhizosphere. 1. *Heterogeneous water availability is a typical characteristic of soils. Water content in soil is spatially variable and also has a large temporal dynamics. Despite the intrinsic heterogeneity of soil-plant water relations, we know little about the ways how plants respond to local environmental properties. To monitor root responses soil water heterogeneity and effects of water heterogeneity on root water uptake we used neutron radiography, especially suited to detect water distribution, to non-invasively image root growth and 2-D soil water distribution as time-lapsed images. Lupin plants were grown in 30*25*1 cm³ aluminum containers. The root zone was partitioned to nine compartments separated by capillary barriers. Two weeks after planting, watering was stopped in the right side while the middle and left compartments were kept wet. Daily changes in water content and root distribution in each compartment have been monitored by neutron radiography for 15 days. Neutron radiography showed that the interactions between roots and surrounding soil significantly varied over time and there is a significant response of roots to soil water distribution. Root growth in the drying compartment remained equal to that in the wet compartment, until the conditions became limiting. For a particular range of low water content, root growth in dry parts was even higher than in the wet parts. This demonstrates that plants make an effort to occupy more soil volume, probably for extracting more water before conditions become even more limiting. This root response could be observed even in individual roots that crossed both, dry and wet compartments.*

Soil hosts a stunning wealth of biological activity from a large number of species including bacteria, protozoa, and fungi. The dynamics of spread of microorganisms is an important determinant in multiple processes such as the nutrient cycling within soil, the dynamics of plant diseases or even the entire ecosystem functioning. Studying the spatial distribution of microbes in soil is important but challenging due to the opacity of soil and the complexity of biological and environmental factors involved in microbial spread. We are interested in investigating to what extent soil structural heterogeneity at the pore level affects macroscopic microbial invasions. Using a network representation for real soil samples and mathematical models for microbial spread, we show that structural heterogeneity may have a very significant influence on the size of microbial invasions. In particular, neglecting the soil structural heterogeneity may lead to undesired underestimation of microbial invasion. We explain our findings in terms of a crucial interplay between heterogeneity in microbial transmission and heterogeneity in the topology of soil networks. The main influence of network topology is linked to the existence of long channels in soil networks that act as bridges for transmission of certain types of microbes between distant parts of soil. Overall, our theoretical work demonstrates that the shape, size, and interconnection of pores in addition to type of microorganisms, presence of water, and other characteristics influencing the exploration of the soil pore space are the key factors determining the extend of microbial invasion in soil.

QUANTIFYING DISTURBANCE OF SOIL STRUCTURE AT MICROBIAL SCALES IN THE PREPARATION OF BIOLOGICAL SECTIONS

Eickhorst Thilo^[4], Pajor Radoslaw^[2], Baveye Philippe^[3], Otten Wilfred^[2]

^[1]University of Bremen ~ Soil Science ~ Bremen ~ Germany ^[2]University of Abertay Dundee ~ The SIMBIOS Centre ~ Dundee ~ United Kingdom ^[3]Rensselaer Polytechnic Institute ~ Dept of Civil and Environmental Engineering ~ Troy, NY ~ United States ^[4]University of Bremen ~ Dept. of Soil Science ~ Bremen ~ Germany

The mechanisms of microbe-soil interactions and their influence on geochemical processes are poorly understood. Recently, molecular techniques have been introduced to study these sites at the micro-scale by staining the colonizing microbes in 2D-sections of resin impregnated soil. In parallel the analysis of element distributions in undisturbed soil has been combined with non-invasive X-ray computed tomography, which for small samples approximates spatial scales relevant to microorganisms. Restrictions can be found for the insertion of specific probes in order to detect soil microorganisms requiring undisturbed soil samples of less than 15mm in diameter. The underlying assumption of biological thin sections is that these are an undisturbed reflection of the soil microhabitat. To ensure that samples used for this purpose can be regarded as undisturbed as found in nature, the sampling procedures have been evaluated at scales relevant to microorganisms and improved. The degree of disturbance was assessed with the use of X-ray CT. Movements of soil particles in 3D as well as porosity and connectivity were analysed during sampling in different soils. Thin-walled aluminium rings showed to cause minimal disturbances on the scale relevant for the microbial habitat in soil. Nevertheless, naturally formed cracks were influenced significantly whereas the arrangement of particles and pore space in areas in between remained stable. An additional analysis of the same samples is conducted after resin impregnation showing how this process influences the preservation of the soil structure. This study presents technical requirements allowing the investigation of soil heterogeneity on the microscale and its influence on bio-geochemical processes.

There are three main approaches to model or reconstruct (using some limited information or properties) some porous media: 1) statistical methods (correlation functions and simulated annealing, multi-point statistics, entropy methods), 2) sequential methods (sphere or other granular packs), and 3) morphological methods. In this contribution we analyze all these methods and show that correlation functions have some substantial advantages. Main results and discussions include: 1) characterization and classification of soil 2D and 3D structure using different correlation functions (two-point probability, linear and cluster functions), 2) reconstruction of soil structure based on its correlation functions, 3) reconstruction of 3D soil structure from 2D cut(s), 4) reconstruction quality control using morphological and other statistical methods, 5) approaches to deal with soil anisotropy and hierarchical levels. All examples come from real soil samples obtained via conventional thin-sectioning or X-ray microtomography.

Soils are four dimensional natural bodies with the key characteristic of spatio-temporal variation in state properties and processes. This holds true for a large span of spatial scales, but landscape scale has received more and more attention, mainly because this is the spatial scale where man-made activities take place, e.g., agriculture, forestry. Soil landscapes are critical, because of the match in spatial scale with activities of man. In the talk we will give a short overview on definitions and principles of landscape analysis including processes, drivers, and structures. Different types of landscape scale modelling will be addressed. Few examples on the coupling between structure and process dynamics will highlight the importance of landscape scale. Combining progress in analysing soil landscape structures with detailed process studies (including modelling) improves our understanding of regional and global biogeochemical processes and should strengthen soil science in the earth sciences community.

The soil erosion and the decrease in soil organic carbon (SOC) content have been identified in 2006 by the European Commission as two of the major threats on European soils. Soil erosion and SOC are closely related, and their spatial variability and temporal dynamics are strongly affected by natural and anthropogenic processes occurring at the landscape scale. This study aims to model simultaneously the soil depth evolution (erosion and accumulation) and the SOC dynamics at the landscape scale over 100 years. The study area was situated within a complex agricultural hedgerow landscape (NW France), with varying soil parent material, slopes, soil depth, field size and land use. We estimated in a previous study the initial depth of soil and SOC stocks. We used a soil evolution model, coupling a SOC dynamics model based on RothC and a soil erosion and accumulation model called Landsoil model. We modeled the soil evolutions under two climate scenarios: a stationary scenario where climate is similar to that observed in the past 30 years, and a climate change scenario corresponding to the A1B emissions scenario of the Intergovernmental Panel on Climate Change. Moreover, different scenarios of land use and farming practices were applied. We will discuss the combined effects of land use, farming practice and climate on soil evolution (soil depth and SOC), considering both the general evolution of the soil properties at the study site scale and their spatial distribution.

^[1]National Research Council of Italy (CNR) ~ Institute for Mediterranean Agricultural and Forestry Systems (ISAFOM) ~ Ercolano (NA) ~ Italy ^[2]University of Naples Federico II ~ Dept. Agricultural Engineering and Agronomy ~ Portici (NA) ~ Italy ^[3]University of Naples Federico II ~ Department of Soil, Plant, Environmental and Animal Production Sciences ~ Portici (NA) ~ Italy

The effect of climate change on the sustainability of irrigated agricultural systems will be different from area to area depending from some factors as: (i) water availability, (ii) crop water demand (iii) soil hydrological behavior and (iv) irrigation management strategy. The adaptation of irrigated crop systems to future climate change can be evaluated by means of physically based model which simulate the soil-water-plant and atmosphere system. In the irrigated areas, the irrigation strategy determines whether and how climate signal is observed. When water availability is not limited, and crop water requirements can be fully met by irrigation, the influence of a (moderately) warmer and drier climate on production can be offset by irrigation. Therefore climate signal translates into higher water consumption. The interaction between climate change, soil spatial variability, irrigation strategies and crop responses to water availability (maize, fennel) at local scale was examined in the present work. Simulation studies were performed in an area of 183 ha of Sele plain (Southern Italy), characterized by an high soil spatial variability (17 representative soils was described), by means of agrohydrological model CropSyst (crop growth, water and nitrate soil balance were calibrated and validated). Two scenarios were considered, current climate (1961-1990) and future climate (2021-2050), the latter from a statistical downscaling technique applied to GCMs. Different irrigation schedules, optimal (realized by the model) and local irrigation management (fixed irrigation), were simulated. Crop production and nitrogen leaching determined by different climatic scenarios, soil and irrigation management were analyzed.

S04.04 -4

A COUPLED SOIL PROCESS AND FERTILISATION MODEL TO PREDICT NUTRIENT SOIL CONCENTRATIONS IN REGIONAL AGROECOSYSTEMS

Gärtner Dominique^{*[1]}, Della Peruta Raniero^[1], Keller Armin^[1]

^[1]Swiss Soil Monitoring Network (NABO) ~ Federal Research Station for Agroecology and Agriculture (Agroscope ART) ~ Zürich ~ Switzerland

Many environmental models have been developed to understand the soil system at landscape scale. Often these models include environmental variables of the biophysical systems such as soil, vegetation, climate or hydrosphere, but neglect the spatial heterogeneity of agricultural management practices. In addition, the spatial units of the process based environmental model usually don't match the ones of the agricultural system, e.g. fields or farms. Therefore, one main challenge of modelling nutrient cycling in agricultural soils at landscape scale is to include geo-referenced land management practices. We developed a regional spatially explicit fertilization model that provides animal manure and mineral fertiliser application rates and fertiliser types at landscape scale at a spatial resolution of one hectare for Swiss agroecosystems. The model is based on geo-referenced Swiss farm census data and Swiss land use statistics. The model was applied for the agricultural soils of the Canton Fribourg, Switzerland (77.000 ha), managed by 3376 farms. The fertilization model calculates the nutrient inputs for the time period 1980-2007 on an annual basis. The fertilization model is linked to a simplified soil process model that simulates the fate of the nutrients in soil in the long-term. Coupling both models provides a better insight of both the soil system and nutrient cycling in agroecosystems at the landscape scale.

Reina Mercedes, 10, 41012 ~ Land Evaluation Unit ~ Seville ~ Spain

According to the Kyoto Protocol, land use (LU) planning must consider strategies to maximize soil C stock (SCS) through LU change and management practices. This research presents a land evaluation tool (Carbosoil) for predicting soil capacity for storing organic carbon, as a new component of MicroLEIS DSS. The pilot study area was a Mediterranean region (Andalusia, Southern Spain) during 1956-2007. Input data were obtained from different data sources and include 1689 soil profiles from Andalusia (S Spain). Previously, detailed studies of changes in LU and vegetation carbon stocks, and soil organic carbon (SOC) dynamic were carried out. Previous results showed the influence of LU, climate (mean temperature and rainfall) and soil variables related with SOC dynamics. For instance, SCS decreased in Cambisols and Regosols by 80% when LU changed from forest to heterogeneous agricultural areas. Taking this into account, the input variables considered were LU, site (elevation, slope, erosion, type-of-drainage, and soil-depth), climate (mean winter/summer temperature and annual precipitation), and soil (pH, nitrates, CEC, sand/clay content, bulk density and field capacity). The available data set was randomly split into two parts: training-set (75%), and validation-set (25%). The model was built by using multiple linear regression. The regression coefficient (R^2) obtained in the calibration and validation of Carbosoil was >0.9 for the considered soil sections (0-25, 25-50, and 50-75 cm). The validation showed the high accuracy of the model and its capacity to discriminate the most suitable areas for maximizing C sequestration under different climate, LU and soil management scenarios.

S04.04 -6

THE SOIL MAP PARADIGM: THE PRODUCTION OF VERIFIABLE DIGITAL LANDSCAPE PROJECTIONS VERSUS COMPLEX-CODED EXPERT VIEWS

Baritz Rainer*^[1]

^[1]Federal Institute for Geosciences and Natural Resources (BGR) ~ Groundwater and Soil ~ Hannover ~ Germany

Modern GIS techniques allow the processing of large amounts of high resolution soil data: large areas covered by high resolution soils maps (e.g. 1:50,000) can be easily processed, and large amounts of plot-level measurements can be accurately upscaled using high-resolution digital elevation models. Both kinds of data exist in Europe in astonishing densities, but yet are not available. The number of map applications producing policy-relevant spatial information at continental and national level is often limited to a set of simple pedo-transfer rules. The comparability of data sets is also limited, especially beyond country borders, terminologies not described, and mapping rules usually not documented. This makes it difficult to validate soil landscape delineations, and legacy mapping data thus seem to be of limited value for example to cross-validate digital soil mapping. Recently, other approaches such as the use of radiometric data sets are becoming re-discovered, and satellite data for the mapping of soil properties in areas sparsely covered by vegetation are being intensively investigated. Data harmonization activities, the building of new data bases, has largely ceased in Europe; at parallel, initiatives for developing new high-resolution data sets based on digital soil mapping including remote sensing seem to gain importance. This presentation will attempt for building a conceptual umbrella over the possible future of soil data development, harmonization, networking and data exchange in Europe.

S04.04 -7

A REGRESSION KRIGING APPROACH TO PREDICT SOIL SURFACE PROPERTIES IN A MEDITERRANEAN BASIN

Blaschek Michael^[1], Swen Meyer^[2], Ludwig Ralf^[2], Duttmann Rainer^[1]

^[1]Christian-Albrechts-University Kiel ~ Department of Geography ~ Kiel ~ Germany ^[2]Ludwig-Maximilians-University Munich ~ Department of Geography ~ Munich ~ Germany

Environmental planning and modelling is highly dependent on reliable information about the spatial distribution of physical and chemical soil properties. In order to obtain continuous soil data in high resolution various pedometric techniques have been applied successfully on different scales and in different types of landscape. The main objective of this study was to compare regression kriging (RK) with several basic deterministic and geostatistical approaches to predict physical and chemical topsoil properties in an undulating, 16km²-sized river catchment near Ussana (Sardinia, Italy). We further investigate whether the application of more complex non-spatial digital soil mapping techniques such as artificial neural networks or regression-tree models may lead to better prediction outcome. The survey based on 197 point measurements from a locally adjusted stratified random sampling and a set of co-variables derived from a 10m resolution DEM (SAR) and a geological map at 1:25000 scale. Model efficiency is evaluated by the normalized root mean square error based on leave-one-out cross-validation and maps of spatially distributed errors. First results indicate that RK performs best wherever ancillary attributes were moderately correlated to the target variable. For instance, the spatial prediction of total C could be improved by 7% compared to ordinary kriging with an explained variance of approximately 41%. Thus, assuming readily available continuous information on soil forming factors such as geology and relief, hybrid methods like RK are fast, efficient and comprehensible tools to provide modellers and decision makers with soil-related parameters of high quality.

S04.04 -8

DERIVATION OF POTENTIALLY DRAINED AREAS IN THE STATE OF SCHLESWIG-HOLSTEIN/GERMANY

Kuhr Petra*^[1], Tetzlaff Björn^[1]

^[1]Forschungszentrum Jülich GmbH ~ IBG 3 ~ Jülich ~ Germany

Especially in modeling of nutrient inputs into groundwater and surface waters artificial drainage systems are a main input pathway for nutrients. In large scale analyses information about the spatial distribution of artificial drained areas are missing. With general information from soil data, land use data and relief parameter, areas can be located where artificial drainage is most likely. In the federal state of Schleswig-Holstein no area covering soil data were available. Therefore the needed parameters had to be derived from three different scaled data sets. These data were field scaled data from land taxation in the 1960s, which is only covering field sites with arable land and grassland. A second data set was a digital soil map at the scale of 1:25.000 which provided the most valuable information but was only existent for half of the state area. The third data set was a small scaled soil map at the scale of 1:200.000. This map was covering the total area of Schleswig-Holstein but it was too imprecise to be used in nutrient modeling due to the small scale. In this study we used the three different soil data sets under consideration of additional information about relief and actual land use to derive area covering data sets with information about soil type, groundwater influence and stagnant moisture. Together with land use parameters and the localization of drainage channels these parameters could be used in the analyses of parameter combinations which are typical for artificial drainage.

^[1]IRD-Montpellier ~ INRA-IRD-SupAgro, UMR-LISAH, 2 place Viala ~ Montpellier ~ France ^[2]IRD ~ UMR-LISAH, 2 place Viala ~ Montpellier ~ France ^[3]Montpellier SupAgro ~ UMR-LISAH, 2 place Viala ~ Montpellier ~ France ^[4]INRA ~ UMR-LISAH, 2 place Viala ~ Montpellier ~ France

Modelling is an appropriate methodology for understanding space-time evolution in soil and landscape processes. Such modelling presumes the ability to produce quantitative models of soil redistribution in the landscape to test the effects of different scenarios of land management and climate evolution. The LandSoil model (Landscape design for Soil conservation under soil use and climate change) is designed for the analysis of agricultural landscape evolution at a fine spatial resolution scale [1-10 meters] and a mid-term temporal scale [10-100 years]. Based on the Stream model, LandSoil is suitable for simulations from parcel to catchment scale. It is spatially distributed, event-based, and considers water and tillage erosion processes. Specificity of the model is the use of a dynamic representation of the agricultural landscape through parameters such as a monthly representation of soil surface properties, hydrologic pathways and accounting a climate component based directly on rainfall events. We present the characteristics of the model, sensitivity analysis to the main erosion processes parameters and its application to a scenario study on a Mediterranean site. Sensitivity analysis shows the importance both of soil surface properties and flow connectivity on catchment soil redistribution, allowing make decisions and planning soil and water conservation strategies. Catchment scale simulations on a degraded scenario, maximising the hydraulic conductivity whit the removal of all the grass bands between fields, indicate a global increase of the soil erosion rate (+29%), with spatial variability depending on the specific soil use type and a significant loss of trapping efficiency at field borders (-81%).

ROOT-MEDIATED MOBILIZATION OF SOIL PHOSPHATES: WHAT DID WE LEARN FROM MECHANISTIC MODELLING?

Gerard Frederic^{*[1]}

^[1]INRA ~ UMR Eco&Sols ~ Montpellier ~ France

Phosphorus is limiting plant growth in many soils. The perspective of scarcity of the P-ore (phosphate rock) reserves urges us to find an alternative to P fertilization, or at least to decrease it while keeping the same yield. An option is to solubilise soil P (i.e. to increase P availability) by relying on the interactions between roots activity (exudation of proton/hydroxyl, organic ligands, etc.) and P-containing soil constituents. However, P-mobilizing processes and mechanisms are poorly known and understood. Mechanistic modelling can be profitably used to fill this gap. The present communication is aimed at reviewing our recent works where we propose a mechanistic equilibrium model for simulating P availability in soil and rhizosphere. We studied neutral oxisols with contrasted mineralogical composition and P fertilization levels. A new root-mediated process, the uptake of Ca ions, was found to play a key role, as it markedly increased P availability in the rhizosphere of Durum wheat as pH increased. Model's validity was demonstrated by modelling P availability over a range of pH values and salt concentrations.

ARBUSCULAR MYCORRHIZA – CONNECTING CARBON AND PHOSPHOROUS DYNAMICS IN SOIL

Kleinmann Joachim^{*[1]}, Zielinski Frank^[2], Banitz Thomas^[1], Frank Karin^[1], Johst Karin^[1], Fester Thomas^[2]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Ecological Modelling ~ Leipzig ~ Germany ^[2]Helmholtz Centre for Environmental Research - UFZ ~ Environmental Microbiology ~ Leipzig ~ Germany

Arbuscular mycorrhizal (AM) fungi are ubiquitous in terrestrial ecosystems and can colonize more than 80 % of all terrestrial plants. Therefore this plant-fungal symbiosis represents one of the most important soil-atmosphere interfaces and couples the nutrient fluxes of carbon (C) and phosphorous (P). However, not much is known so far about the resulting C and P-dynamics and their interactions with related soil organisms. To close this gap, we started a spatially explicit modelling approach, which simulates the growth of extraradical mycelia of AM fungus *Glomus intraradices* (DAOM 197198) in dependence of C and P availability. Due to its obligate biotrophism, we assume *Daucus carota* (wild carrot) as plant partner, implicitly simulated as a P-C exchange point. The fungus acquires P from the soil, uses it as growth nutrient, stores it in spores and exchanges surpluses for C, which is further needed for P uptake and maintenance. Depending on the underlying mechanisms, the model results in different C and P-dynamics. This enables us, together with corresponding experiments, to identify possible mechanisms of resource use and interaction. We observed that limiting factors of growth are changing in time and space, and identified three stages of C and P use in the fungus: (1) Growth: C and P are predominantly used as nutrients. (2) P-Uptake: C is predominantly used for P acquisition. (3) Sporulation: C and P are stored in spores. These three stages facilitate understanding of C and P-fluxes in this soil-plant-fungus system and the resulting interacting dynamics of these nutrients.

A THEORETICAL APPROACH TO PREDICTING SHIFTS IN PLANT-MYCORRHIZAL INTERACTIONS AND SOIL CARBON FEEDBACKS

Bryant Jessica A. M.^{*[1]}, Post Wilfred M.^[2], Classen Aimee T.^[1]

^[1]University of Tennessee ~ Ecology and Evolutionary Biology ~ Knoxville ~ United States ^[2]Oak Ridge National Laboratory ~ Environmental Sciences Division ~ Oak Ridge ~ United States

Interactions between plants and their symbiotic mycorrhizal fungi are at the interface of above and belowground systems and their interactions can influence soil carbon (C) dynamics. Plants allocate a portion of their C to mycorrhizae, where it becomes hyphal biomass; in return, mycorrhizal fungi increase plant water and nutrient uptake. However, when plants become stressed the symbiosis can breakdown. When plants are stressed they reduce their C allocation to mycorrhizae; mycorrhizae then shift to gain C via soil organic matter (SOM) degradation. This can cause a soil C shift where the plant-mycorrhizal interaction becomes a source of C to the atmosphere instead of a sink. The magnitude of the effect of ectomycorrhizal C acquisition, whether from plants or SOM, is crucial to predicting soil C efflux and storage. We developed a theoretical model that predicts soil C dynamics following a shift in the plant-mycorrhizal C interaction. Following a reduction in C allocation to roots, our model predicts changes over time in five C pools: aboveground biomass, roots, litter, fungal biomass, and soil. Analysis of model dynamics allowed us to identify the range of parameter values required for the interaction between plant allocated C, ectomycorrhizal metabolism, and soil C for the system to switch to a C source. Preliminary parameter sensitivity analysis shows that decreases in C allocation to roots and mycorrhizal fungi significantly alters all of the C pools represented in the model.

COMPARING MODELING APPROACHES FOR CLAY MIGRATION

Michel Eric^[1], Finke Peter^[2], Cornu Sophie^[3]

^[1]INRA ~ UMR1114 INRA-UAPV Environnement Méditerranéen & Modélisation des Agro-Hydrosystèmes ~ Avignon ~ France ^[2]Ghent University ~ Geology and Soil Science ~ Gent ~ Belgium ^[3]INRA ~ UR1119 Géochimie des Sols et des Eaux ~ Aix-en-Provence ~ France

Operational models to simulate clay migration over pedogenesis (multi-millennium) timescales are rare, and utilize concepts for mobilization, transport and immobilization of colloidal matter that were developed and tested for applications at limited temporal extents only. Comparison of different concepts at both short and pedogenesis timescales is needed to evaluate the detail of process description needed at both scales. We compared the functional clay mobilization approach by Jarvis et al. (1999) to the mechanistic approach by Michel et al. (2010) by embedding both approaches in the SoilGen model (Finke, 2011). The models were compared with respect to the accuracy with which they could reproduce short time lab experiments as well as by their ability to produce a E-Bt horizon sequence in loess soils and the accuracy of simulated clay content profiles after 15000 years of soil formation. The evolution of soil structure is one main feature of pedogenesis. Biological processes such as faunal or root bioturbation influence the structure of the soil ecosystem. However the soil biological activity is also largely impacted by the spatial organisation of soil (aggregation, pore connectivity). Simulation-based approach is an interesting way to explore the interactions between an evolving soil structure and bioturbation activity as well as to assess the sustainability of soil systems. Our main objective is to develop a 3D multi-scale model to represent the evolution of soil structure. It is a generic soil structure allowing calibration on various measured data (mineral and organic size distribution, bulk density...) and the choice of the constituting elements (mineral and organic matters, pores, nutrients...). Virtual processes can be introduced in this structure to model soil functioning. Our applied case study concerns soil rehabilitation by soil construction (constructed Technosol). Firstly, this work deals with the representativeness of an existing structure model: the APSF (Arborescent-Pore-Solid-Fractal). It is a discrete pattern-based soil design. The preliminary exploration analysis shows that the calibration of the APSF on size distributions and bulk densities is very sensitive. Comparison with measured data on pore network could allow a better assessment of the parameters. Secondly, we integrated the APSF into a multi-agent system (MAS) in order to model the interactions of soil structure with anecic earthworms. We will present the developed model based on SWORM (Simulated Worm) as well as its first results. Hints to model root growth in MAS are also presented.

^[2]Rothamsted Research ~ Department of Sustainable Soils and Grassland Systems ~ Harpenden ~ United Kingdom

^[3]Rothamsted Research ~ Department of Sustainable Soils and Grassland Systems ~ North Wyke ~ United Kingdom

We describe a dual porous model of soil, constructed with the Pore-Cor network model and its successor Porexpert, that closely reproduces the entire water retention characteristic together with meso and macro-porosity, and aggregate size distribution. In order to use the model for the a priori biophysical simulation of denitrification, we constructed a single critical percolation channel, adjacent to which between 1 and 10 micro-porous 'hot-spot' zones of biological activity were positioned. Nitrification and denitrification reactions within the hotspots were assumed to follow Michaelis-Menten kinetics. The pore network was fully saturated following addition of an aqueous 'amendment' of nitrate and glucose which started the reactions. Diffusion coefficients for Fickian and Crank-Nicolson calculations were taken from the literature, and corrected for tortuosity. Adjustment of the rate coefficient and oxygen threshold concentrations, within the context of a sensitivity analysis, gave carbon dioxide, nitrous oxide and molecular nitrogen emission curves in good agreement with previous experimental measurements, and revealed information about the positional relationship of hotspots relative to the critical percolation path. This work was part of the Soil Programme for Quality and Resilience (SPQR) of the UK Biotechnology and Biosciences Research Council (BBSRC). MODELING CARBON DYNAMICS AND MCPA DEGRADATION AT THE SOIL-LITTER INTERFACE

Pagel Holger^[1], Poll Christian^[2], Ingwersen Joachim^[1], Kandeler Ellen^[2], Streck Thilo^[1]

^[1]University of Hohenheim, Institute of Soil Science and Land Evaluation ~ Biogeophysics ~ Stuttgart ~ Germany

^[2]University of Hohenheim, Institute of Soil Science and Land Evaluation ~ Soil Biology ~ Stuttgart ~ Germany

*The detritosphere (soil close to soil-litter interface) is characterized by a high availability of litter-derived organic substrates stimulating microbial growth and activity. To improve the understanding of regulation mechanisms, which are responsible for stimulated pesticide (here MCPA) degradation in the detritosphere, we developed a new model. The model simulates transport and degradation of pesticides and accounts for the sizes of 12C, 13C and 14C carbon pools as well as the activities of the total and specific soil microbial communities. Fungal MCPA degradation was modelled by a co-metabolic kinetic approach. A global sensitivity analysis was performed to identify the high-leverage model parameters. The most crucial role for model dynamics played the fraction of decomposed litter C transferred to soil and the initial bacteria/ fungi ratio. For model calibration, we conducted a microcosm experiment with 14C-MCPA (50 mg kg⁻¹) amended soil. We set up three experimental treatments: i) maize litter (control), ii) MCPA and iii) MCPA + maize litter. The litter was placed on top of small disturbed soil cores and the microcosms were incubated at 20 °C for 20 days. During incubation we analysed total CO₂, 13C-CO₂ and 14C-CO₂. Soil cores were sampled on five dates using a stratified sampling scheme and analysed for MCPA, dissolved organic carbon, microbial biomass, 16s rDNA and the functional gene *tfdA* as a proxy for the population of bacterial MCPA degraders. We will present the new model and discuss simulations and parameter sensitivities against the background of the data from the microcosm experiment.*

BIOGEOCHEMICAL PROCESSES AND HOTSPOTS IN HETEROGENEOUS VADOSE ZONE

Mohanty Binayak*^[1]

^[1]Texas A&M University ~ Biological and Agricultural Engineering ~ College Station ~ United States

A fundamental issue in predicting fate and transport of contaminants in subsurface systems is the complex interaction between transport and redox processes. These predictions are further complicated by variable flow dynamics, transient redox states, and structural heterogeneity of the unsaturated zone. Thus, the objective of this study is to evaluate the effect of varying hydrologic conditions on coupled biogeochemical processes in soil columns with known structural heterogeneity and background geochemistry. In particular, redox geochemistry within repacked homogeneous sand and loam columns is compared with a layered sand-over-loam configuration. Numerical perturbations corresponding to rainfall intensity, water chemistry (pH), and variations in hydrologic boundary conditions are conducted using HP1. Modeling results indicate that the dominant biogeochemical process is advective transport for homogeneous sand, reduction of iron from nitrate for homogeneous loam, and iron and sulfate reduction for the layered column. Findings suggest that redox gradients in the homogeneous columns are controlled by the type of hydrologic boundary condition (infiltration, drainage, etc.) whereas textural layering is paramount in controlling redox gradients in the layered column. This textural interface enhances biogeochemical activity in the layered column and highlights the need to incorporate structural heterogeneity in contaminant fate and transport models.

COMPARISON OF TWO MODELLING APPROACHES FOR WATER TRANSFER IN THE SOIL-VEGETATION-ATMOSPHERE CONTINUUM

Guaus Anaïs^{*[2]}, Bsaibes Aline^[3], Auffray Valérie^[3], Lebon Eric^[4], Gérard Frédéric^[2]

^[1]INRA ~ UME Eco&Soils ~ Montpellier ~ France ^[2]INRA ~ UMR Eco&Sols ~ Montpellier ~ France ^[3]ITK ~ ~ Montpellier ~ France ^[4]INRA ~ UMR Lepse ~ Montpellier ~ France

As part of a R&D project aiming at providing vineyard managers with a computer-based decision support system for optimizing irrigation, we discuss the validity of two modeling approaches for water transfers in the soil-plant-atmosphere continuum. The two models are an empirical 'bucket-like' model and a mechanistic model based on the 1D Richards' equation. The practical context implying that soil-water parameters are poorly estimated, both models are compared in terms of accuracy and parameterization cost. The models are coupled to the same canopy growth, radiation absorption, evaporation and transpiration models, and the predawn leaf water potential (PLWP) is used as the indicator of soil-water deficit. The parameters of both models are estimated with pedotransfer functions from the single texture and the only additional input for the 1D model is root repartition versus depth. A multi-factor sensitivity analysis relative to the input parameters of the soil-vegetation-atmosphere coupling shows that the hard-to-obtain rooting depth is the key factor of the PLWP sensitivity. It also shows that the computation of PLWP with the 1D model is robust against root distribution uncertainty, so that root distribution can be fixed to a mean value. The accuracy of the two models is evaluated in vineyards varying in soil type, rooting depth and irrigation procedure in the Languedoc region (France), by comparing simulated to measured values of vine transpiration and PLWP. Provided the calibration of rooting depth, both models give results coherent with field measurements, with no significant improvement when the more physical mechanistic model is used.

SCENARIO MODELLING OF ECOSYSTEM SERVICE PROVISION WITH A NEW SOIL MODEL (MOSES)

Aitkenhead Matt*^[1]

^[1]*The James Hutton Institute ~ Computation & Information Sciences ~ Scotland ~ United Kingdom*

A new process-based soil model (MOSES – Modelling Soil Ecosystem Services) is described. The model is designed to provide information about a soil profile at approximately 1-cm depth resolution, on a 1 minute timestep. Conceptualisation of the model has targeted a set of soil ecosystem service-related functions, including carbon sequestration, water buffering and biomass productivity. A wide range of physical, chemical and biological processes have been implemented within the model, and output parameters are interpreted in relation to a range of ecosystem services. Validation of the model against detailed time-series field measurements at a number of sites has shown it to be effective at simulating a number of specific parameters. We have carried out a number of scenario simulations on changing land cover and climate for a range of different soil types/environmental conditions, and have shown how potentially useful MOSES could be for evaluating potential land management and environmental changes in relation to the provision of multiple ecosystem services. The trade-offs between different services changes under different scenarios, demonstrating the ability to explore candidate land management strategies for the optimisation of ecosystem service provision.

Soils and landscapes evolve simultaneously. Soil evolution is controlled by redistribution and transformation processes influenced by topographic and climatic parameters, with also a major contribution of management strategies. The perennial landscape features have a strong influence on soil spatial distribution (geometry) and soil genesis. Building landscapes which enhance soil resilience to degradation processes and increase soil services appears as a promising way to adapt to forthcoming climatic and land use evolutions. The presentation aims to synthesize major results from a research program nicknamed Landsoil which focused on the evolution of agricultural soils over medium time scales (decades to centuries) in relation to changing conditions of land use and climate. Precise study of the soil 3D organization in three contrasted landscapes (Brittany, Touraine, Languedoc-Roussillon) enabled to link soil redistribution in space to landscape components (field geometry, hedges or ditches network) and their past evolution. A dynamic and high resolution spatial modeling approach was developed coupling erosion processes and soil organic matter evolution and was calibrated over past evolution using dating techniques (Cs137, C14, OSL). The resulting Landsoil model was afterwards applied in a prospective manner under different scenarios of land use and climate change over the 21th century. Indicators of soil vulnerability and soil resilience were defined and tested by the comparison of several prospective scenarios applied on a same landscape and by comparison of the contrasted landscapes.

A HYBRID DESIGN-BASED AND MODEL-BASED SAMPLING APPROACH TO ESTIMATE THE TEMPORAL TREND OF SPATIAL MEANS OF SOIL PROPERTIES

Brus Dick*^[1]

^[1]WUR/Alterra ~ Soil ~ Wageningen ~ Netherlands

This paper launches a hybrid sampling approach, entailing a design-based approach in space followed by a model-based approach in time, for estimating temporal trends of spatial means or totals. The underlying space{time process that generated the soil data is only partly described, viz. by a linear mixed model for the temporal variation of the spatial means. The model contains error terms for model inadequacy (model or process error) and for the sampling error in the estimated spatial means. The linear trend is estimated by Generalized Least Squares. The covariance matrix is obtained by adding the matrix with design-based estimates of the sampling variances and covariances and the covariance matrix of the model errors. The model parameters needed for the latter matrix are estimated by REML. The error variance of the estimated regression coefficients can be decomposed into the model variance of the errorless regression coefficients and the model expectation of the conditional sampling variance. In a case study on forest soil eutrophication, inclusion of the model error led to a considerable increase of the error variance for most variables. In the topsoil the contribution of the process error to the standard error of the estimated trend was much larger than that of the sampling error. For pH there was no contribution of the model error. Important advantages of the presented approach over the fully model-based approach are its simplicity and robustness to model assumptions.

THE VARIABILITY OF SOIL BULK DENSITY, AND ITS IMPLICATIONS FOR SOIL MONITORING.

Lark Murray^{*[1]}, Rawlins Barry^[1], Robinson David^[2], Robinson Inma^[2], Tye Andrew^[1]

^[1]British Geological Survey ~ ~ Nottingham ~ United Kingdom ^[2]Centre for Ecology and Hydrology ~ ~ Bangor ~ United Kingdom

Bulk density is a fundamental soil property. It is important in soil monitoring and inventory because of its significance as a quality indicator and because of its usefulness in predicting harder-to-measure soil properties through pedotransfer functions. It is also essential for the conversion of gravimetric soil data to a volumetric basis, which is necessary for the calculation of nutrient or carbon stocks. Historically not all soil inventories have recorded bulk density, but recent recommendations for national-scale monitoring networks include it among the variables to be measured. Two questions need to be addressed. First, can soil bulk density be predicted with adequate precision by pedotransfer functions when direct observations are not available? Second, how many measurements of bulk density must be made at each site in a monitoring network to provide information of adequate precision? We address these questions in this paper, paying particular attention to how error in estimated bulk density propagates through the calculation of soil carbon stocks. We report an evaluation of some common pedotransfer functions for soil bulk density at national scale in England and Wales, and at local scale in two intensively measured sites, one on peats and organo-mineral soils in the uplands of Wales and one on mineral soils in arable use in Eastern England. Data on bulk density from these two study sites were analysed with linear mixed models, and we report the implications of these results for sampling requirements at site scale.

S04.06 -3

AN EFFICIENT DESIGN FOR MONITORING FOREST SOILS

Ouimet Rock*^[1]

^[1]Ministère des Ressources naturelles et de la Faune ~ Direction de la recherche forestière ~ Quebec City ~ Canada

Forest soils are particularly difficult to monitor because of their great variability in natural ecosystems. Moreover, sampling forest soils precludes the future use of the exact sampling points since sampling causes a disturbance that confounds the prior sampling effect with the time effect. Even the distance of the sampling point from neighbouring trees is reflected in the chemical properties of the sample. To be able to detect soil changes over time, we designed a new spatial sampling scheme for the Quebec Forest Ecosystem Study and Monitoring Network (RESEF). It provides control over spatial, tree, and time variations, permitting unbiased soil monitoring assessment over the long term (design lifespan: ~200 yrs). Its unique design contrasts with other forest soil monitoring projects that have been carried out in eastern North America. Installation of the monitoring set up started in 2002, and the second round of sampling starts in 2012 (sampling interval: 10 years). The typical sampling site is a square 400 m². Trees are positioned and their characteristics are measured. Particular attention is spent to characterize dead standing and fallen trees. The statistical treatment of the monitoring data is now more straightforward, with the possibility to include appropriate variance and covariance component structures in the analyses such as spatial and time dependencies. Effects of environmental variables such as microtopography, distance from trees, and space can thus be isolated from the time effect. Sample and lab analysis method archival is also an important, but neglected, aspect that will be discussed.

S04.06 -4

PEAT DROUGHT RISK IN A CHANGING CLIMATE

Poggio Laura^[1], Gimona Alessandro^[1], Aalders Inge^[1], Hough Rupert^[1]

^[1]The James Hutton institute ~ Aberdeen ~ United Kingdom

Global warming might change the hydrology of upland blanket peats in Scotland with increased risk of drought and release of the stocked carbon. It is therefore important to model the risk of drought in peat areas with estimation of the damage potential. In this study Bayesian Networks (BN) were linked to a Geographical Information System (GIS) to facilitate the spatial explicit modelling of all the relevant parameters. Remote sensing data were integrated in the framework to define input data. The framework was developed using open source software supporting the Open Source Geospatial Foundation (OSGeo). The model was applied to Dava bog in the North-East of Scotland where a historical survey is available providing detailed data on peat depth and water content. The changes in water content as seen from MODIS were modelled as a function of the depth of the peat in 2003 a dry year as example of future extreme events. The preliminary results show that it is possible link BN with GIS to model spatially explicit variables and demonstrate the usefulness of including remote sensing data for monitoring of soil in a climate change context.

LONG-TERM SOIL MONITORING IN GERMANY: IDENTIFICATION OF TEMPORAL AND SPATIAL PATTERNS

Schilli Carsten*^[1], Lischeid Gunnar^[2], Marahrens Stephan^[3], Rinklebe Joerg^[1]

^[1]University of Wuppertal ~ Soil- and Groundwatermanagement ~ Wuppertal ~ Germany ^[2]Leibniz Centre for Agricultural Landscape Research (ZALF) ~ Institute of Landscape Hydrology ~ Muencheberg ~ Germany ^[3]German Federal Environmental Agency ~ soil state and soil monitoring ~ Dessau ~ Germany

The long-term soil monitoring program in the Federal Republic of Germany exists since 1985 and it covers approximately 800 sites under different land use. More than 60 biological, physical and chemical parameters were measured at soil samples of different horizons to a depth of up to two meters. During long-term soil monitoring a large and heterogenic data set was generated. In this study, we have analyzed the soil monitoring data of entire Germany the first time using multivariate statistics. Our study aimed on the identification of temporal and spatial pattern influencing the contents of organic carbon, nitrogen, pH as well as cadmium, chromium, copper, lead, nickel, and zinc. We have used as statistical approach the Self-Organizing Map (artificial neuronal network) with Sammons Mapping was used. Thereby different spatial and temporal pattern could be identified. As main drivers of the heavy metal content in soils of Germany we have identified the parent material and the deposition. The identified temporal trends could be divided, depending on land use. There are clear hints of decreasing heavy metal contents in arable soils and increasing contents in afforested soils with time. The used approach is general enough to describe the spatial influence of e.g. parent material and land use specific temporal trends for the entire area of Germany, while being still suitable to visualize the general impacts at a single site.

MONITORING SOIL CARBON – IS THERE A RIGHT ANSWER?

Black Helaina^{*[1]}, Lilly Allan^[2], Chapman Stephen^[1], Owen Jason^[2]

^[1]The James Hutton Institute ~ Ecological Science ~ Aberdeen ~ United Kingdom ^[2]The James Hutton Institute ~ Environmental Sciences ~ Aberdeen ~ United Kingdom

Soil carbon is high on a number of agendas. From governments to carbon markets to farmers, people want to know how to measure soil carbon, and whether results from monitoring changes in soil carbon changes are reliable enough to be used in decision-making. In this talk, we take a look the results obtained from a range of different UK monitoring schemes where soil carbon has been measured and where changes in soil carbon have been estimated over extended timescales (20 to 30 year time periods). These schemes include the National Soil Inventory for Scotland, the National Soil Inventory for England and Wales, Countryside Survey, the Resurvey of British Woodlands and the AFBI Soil Survey of Northern Ireland (AFBI). Using data from these schemes, we explore the implications of survey design, sampling strategies, sampling techniques, analytical approaches and conversion factors on the estimation of soil carbon stock (t/ha) and content (g/kg) and in estimating changes in soil carbon over time. From these experiences, we propose a range of actions that could be implemented by the soil science community to improve the estimation, reproducibility and comparability of soil carbon data from soil monitoring programmes.

Knowledge on the chemical speciation of trace elements is essential for the mechanistic understanding and accurate quantitative description of the biogeochemical processes that control their mobility and bioavailability in pristine and contaminated soils. Over the last 20 years, synchrotron-based X-ray absorption spectroscopy (XAS) has developed into a invaluable tool for the investigation of trace elements in soils because it allows determining the oxidation state, local coordination and speciation of a target element in-situ even at trace concentrations and in a highly heterogeneous matrix like soil. Quick-scanning and micro-focused XAS in addition enable studies at high temporal and spatial resolution, respectively. In combination with complementary analytical methods, XAS thus offers unique molecular-level insight into trace element sorption, precipitation, and transformation reactions in well-defined model systems as well as in natural soils. Examples for the application and usefulness of XAS for the study of trace elements will be presented, and future challenges and requirements with respect to the use of XAS for investigating trace element speciation and transformation in soils will be discussed.

**RECENT ADVANCES IN HARD X-RAY FLUORESCENCE MAPPING AND TOMOGRAPHY
OPEN NEW AVENUES FOR BIOGEOCHEMICAL RESEARCH.**

Donner Erica^[1], Koppitke Peter^[2], De Jonge Martin^[3], Howard Daryl^[3], Ryan Chris^[4], Carey Anne-Marie^[5], Paterson David^[3], Naidu Ravi^[1], Lombi Enzo^[1]

^[1]University of South Australia ~ Centre for Environmental Risk Assessment and Remediation ~ Adelaide ~ Australia

^[2]The University of Queensland ~ School of Agriculture and Food Science ~ St Lucia ~ Australia ^[3]Australian Synchrotron ~ X-ray Fluorescence Microscopy ~ Melbourne ~ Australia ^[4]Commonwealth Scientific and Industrial Research Organisation (CSIRO) ~ Earth Science and Resource Engineering ~ Clayton ~ Australia ^[5]University of Aberdeen ~ Institute of Biological and Environmental Sciences ~ Aberdeen ~ United Kingdom

Environmental samples such as soils, plant materials, and biosolids are extremely diverse but share a tendency towards heterogeneity. This poses methodological challenges when investigating biogeochemical processes as large data sets are required to thoroughly explore the system complexity. Laterally-resolved synchrotron x-ray fluorescence (XRF) microspectroscopy has become a key method for the in situ investigation of micronutrients and inorganic contaminants in complex environmental samples. This presentation will demonstrate how recent advances in detector technology are drastically reducing dwell times during scanning, and hence bringing new possibilities to environmental research. Fast scanning allows major issues such as radiation damage of hydrated plant samples to be circumvented, and also significantly reduces temporal beamtime requirements, enabling images to be acquired in minutes rather than hours. It also makes particularly time-consuming techniques such as XRF microtomography increasingly feasible. This is a very powerful technique allowing 2D virtual cross sections and 3D elemental distributions to be imaged in situ in environmental samples such as plant organs. Another very promising new technique that will be demonstrated is XANES imaging, a method for speciation mapping that has recently been trialed for the first time on environmental samples. This technique requires micro-XRF mapping to be conducted at multiple (approximately 80) x-ray beam energies, and due to unreasonable beamtime requirements was not practicable prior to the advent of fast detection systems. Environmental applications of hard XRF mapping are clearly set to grow as the advent of fast detection facilitates the deployment of increasingly powerful imaging techniques.

SHEDDING SYNCHROTRON LIGHT ON INTERNAL STRUCTURES OF SOILS - APPLICATIONS OF ADVANCED X-RAY MICROSCOPY

Peth Stephan*^[1]

^[1]Christian-Albrechts-University ~ Soil Science ~ Kiel ~ Germany

The first applications of synchrotron radiation (SR), which long has been perceived (energetically) as a “waste product”, date back to the mid 1960s. Fundamental and applied research using SR was initially focused in the fields of physics, chemistry, crystallography, and material sciences and later extended to medicine, biology and geosciences. About 20 years ago the first soil scientist began to use SR to study in-situ soil processes. Today more than 50 Light Sources are in operation worldwide offering excellent opportunities to conduct soil research with a variety of SR-based techniques. Synchrotron radiation can be used in many different ways. Besides spectroscopy and fluorescence analysis, synchrotron-based X-ray absorption tomography (SR-?CT) has become a useful tool in soil research. Flannery and his colleagues (Flannery et al. 1987) introduced SR-?CT as a “new form of microscope” providing 3-dimensional images of internal structures with an excellent signal-to-noise ratio and a spatial resolution comparable to that obtained in light microscopes. This presentation outlines the principles of SR-?CT and summarizes some potential applications in soil research going beyond what is achievable with industrial tube-based X-ray systems. A major goal of X-ray microtomography is to obtain an insight into small scale 3D pore networks. Examples for the quantitative analysis of network morphologies, their dynamics with environmental conditions and their influence on spatial heterogeneities of soil compositions will be demonstrated and discussed.

SYNCHROTRON X-RAY AND ELECTRON MICRO-PROBE STUDY OF CONTAMINATED DREDGED SEDIMENTS.

Poitevin Antonine^[1], Louis Hennet^[2], Catherine Lerouge^[3], Guillaume Wille^[4], Philippe Bataillard^[3]

^[1]BRGM - CNRS ~ CEMHTI ~ Orleans ~ France ^[2]CNRS ~ CEMHTI ~ Orleans ~ France ^[3]BRGM ~ EPI ~ Orleans ~ France ^[4]BRGM ~ MMA ~ Orleans ~ France

Sediments originating from periodic dredging of waterways were traditionally disposed of in storage sites without any precautions or treatments. There may be some environmental concerns especially when the dredged material comes from historically contaminated areas such as the North French coal basin. This study aims to characterize the metal mobility in deposited dredged sediment by combining chemical and spectroscopic techniques. Electron probe micro-analyse (EPMA) combined with microbeam x-ray fluorescence (μ XRF) at Synchrotron sources were used to identify Zn and Pb carriers. In particular Zn and Pb distributions in thin-section samples were determined by μ -XRF elemental mappings. EPMA was used to determine the distribution of light elements for which the energy of the emission lines is below 4 keV (Si, S, P...). The presence of reduced (sulphides) and oxidized (sulphates, oxihydroxides) phases strongly suggests that the redox state is one of the major parameters controlling the metal mobility. Therefore x-ray absorption spectroscopy experiments were also performed to study the oxidation state in both bulk samples and on selected regions of interest in thin section samples. In this work, the potential effects of the sample preparation were also studied and will be presented.

SOFT X-RAY SPECTROMICROSCOPY OF NATURAL ORGANICS AFFECTING ACTINIDE MOBILITY – AN OVERVIEW

Plaschke Markus^[1], Jörg Rothe^[1], Thorsten Schäfer^[1], Kathy Dardenne^[1], Melissa A. Denecke^[1], Horst Geckeis^[1]

^[1]KIT ~ INE ~ Karlsruhe ~ Germany

Securing nuclear repository safety requires profound understanding of molecular processes determining the mobility of released radionuclides (i.e., actinides). In this context systematic spectromicroscopy studies have been performed over the last decade. Scanning Transmission X-ray Microscopy (STXM) is an appropriate tool to visualize natural organics and their interactions with metal cations or mineral phases providing excellent spatial resolution down to the nm-level combined with high chemical sensitivity. This chemical speciation information can be obtained from K- or L-edge NEXAFS (Near Edge X-ray Absorption Fine Structure). STXM/NEXAFS investigations are performed at three different endstations: (1) X-1A-STXM, NSLS, USA, (2) PoLux-STXM, SLS, Switzerland, (3) ALS-MES-STXM, LBNL, USA. Moreover, STXM benefits from the ability to characterize environmental samples in thin films of aqueous suspensions or in thin sections. The studies cover various aspects of natural organics and their interactions with metal ions and mineral phases: (a) basic research on model compounds (e.g., polyacrylic acid (PAA)), (b) metal ion interaction with conditioned humic acid (HA) and (c) organic-mineral associations in natural systems (e.g., claystone). Appropriate model compounds are selected helping to assign spectral features in the more complex natural matter. A distinct metal ion complexation effect is visible both in the C1s-NEXAFS of PAA and HA metal ion complexes depending on sample pH. Metal cations are enriched in a HA minority fraction as determined in Eu(III)-HA aggregates. Furthermore, HA are found associated and fractionated on certain mineral phases, e.g., Al-oxides. Characteristic organic-mineral associations are also observed in claystone samples originating from a possible repository site.

ARSENIC SPECIATION AND MOBILITY IN MINING-AFFECTED RIVER FLOODPLAIN SOILS: X-RAY ABSORPTION SPECTROSCOPY AND COLUMN STUDIES

Kretzschmar Ruben^[1], Petar Mandaliev^[1], Christian Mikutta^[1], Kurt Barmettler^[1], Tsvetan Kotsev^[2]

^[1]ETH Zurich ~ Institute of Biogeochemistry and Pollutant Dynamics ~ Zurich ~ Switzerland ^[2]Bulgarian Academy of Sciences ~ National Institute of Geophysics, Geodesy and Geography ~ Sofia ~ Bulgaria

The floodplains of many rivers worldwide are contaminated due to mining and/or industry. We investigated the spatial distribution and chemical speciation of arsenic (As) in soils of the floodplain of the river Ogosta, NW-Bulgaria, a major tributary to the lower Danube. Ogosta river has been heavily polluted with As and other trace elements by mining of Au, Fe, and Pb/Ag ores, with the largest release of ore waste slurries between 1964 and 1979. Soil samples were collected in selected soil profiles and along transects across the floodplains. Arsenic speciation was investigated by bulk As K-edge X-ray absorption spectroscopy (XAS). Additionally, thin sections of undisturbed soils were examined by micro-X-ray fluorescence (μ -XRF) spectrometry and μ -XAS and selected soils were size-fractionated to explore the elemental composition, mineralogy, and As speciation in different particle size fractions. Soil As concentrations in the floodplain ranged from 40 to 37,400 mg kg⁻¹. Bulk and micro-XAS, combined with ascorbate-extractions, revealed that most As was present as As(V) sorbed to poorly-crystalline Fe(III)-oxyhydroxides, with smaller amounts of As bound in arsenopyrite. The most highly contaminated soils probably also contained smaller amounts of ferric arsenates, as indicated by the extremely low molar Fe/As ratios (<4) in the fine particle size fractions (<20 μ m). We are currently investigating the mobility of As in these soils under oxic and anoxic conditions using column experiments. The biogeochemical processes controlling As mobility in these soils will be discussed.

DIGESTATES FROM BIOGASPRODUCTION: CHEMICAL COMPOSITION AND EFFECTS ON PRIMING IN SOILS

Zirkler Doreen^{*[1]}, Kaupenjohann Martin^[1]

^[1]TU Berlin ~ Department of Soil Science ~ Berlin ~ Germany

Recently, the biogas sector is growing rapidly and covers an increasing share of the energy supply. However, the production of biomass for fermentation competes against food production for agricultural space. Thus, the fermentation of organic residues should be preferably developed. Nutrient cycles can be closed by bringing digestates to the soils. So far, little is known about the variability of the elemental composition of these digestates over time and their effects on soil organic matter. We analysed the annual pattern of the concentrations of C, Ca, Cd, Cu, Fe, K, Mg, Mn, Mo, N, Ni, P, Pb, S, Se and Zn in digestates from sewage sludge (sew), slurry (sl), maize silage (ma) and a sewage-sludge-mash-fat-mixture (mix). According to their origin material, digestates show a wide range of element concentrations. The annual variation of some element concentrations of digestates from one particular origin may, however, be as high as the variability of these element concentrations between digestates of different origin. C/N ratios increased in the order $sew < mix < sl < ma$. Recently, respiration experiments with the digestates and a loamy-sandy soil are conducted to study if priming is induced. $\delta^{13}C$ -analyses shall identify the source of emitted CO_2 (digestate- or soil-derived). In a second respiration experiment, we vary the bioavailable C- and N-concentrations in the digestates in order to test, which of the factors is responsible for priming.

S05.01a -2

IMPACT OF ANAEROBIC DIGESTATES ON SOIL PHYSICAL QUALITY BY MEANS OF MICROSTRUCTURAL SHEAR STRENGTH

Holthusen Doerthe^{*[1]}, Jonas-Schasse Silke^[1], Horn Rainer^[1]

^[1]Christian-Albrechts-University Kiel ~ Institute of Plant Nutrition and Soil Science ~ Kiel ~ Germany

Within the EC the use of agricultural products in biogas plants has strongly increased due to the directive 2001/77/EC that contains ambitious targets for the share of renewable resources in energy production. Many of the EC states implemented the directive via feed-in support. In Germany, especially the amendment of the national act in 2004 caused economic incentives for the use of maize for anaerobic digestion. Hence, the amount of plants in Germany more than doubled from 2003 to 2009. The produced sludges are commonly used as fertilizers with high N availability without questioning. However, their impact on physical soil quality seriously lacks knowledge. Some authors already reported deterioration of soil structure in the wake of digestate application especially on sandy soils, and related this effect to high amounts of soluble potassium ions, a pH-lowering impact as well as a priming effect of soil organic carbon. Also, the physical behavior of the sludges themselves is only poorly understood. In our investigations we tested the impact of two digestates percolating through artificial soil samples by means of rheometry (microstructural soil shear strength) and determined destructive (at high concentrations of digestate) as well as stabilizing effects (at low concentrations) on soil stability. In addition, the analysis of the flow behavior of the sludges themselves revealed distinct thixotropy as well as shear-thinning with regard to application. Those facts help to improve the sustainable management of digestates as valuable amendments without spoiling the soil's ability to provide a fertile foundation for plant production.

S05.01a -3

UNDERSTANDING PHOSPHORUS (P) DYNAMICS IN SOILS AMENDED WITH APPLICATION OF DIFFERENT ORGANIC AMENDMENTS USING THE DIFFUSIVE GRADIENTS IN THIN-FILMS (DGT) TECHNIQUE

Kane David*^[1]

^[1]Cranfield University ~ Environmental Science and technology ~ Cranfield ~ United Kingdom

Global P resources are limited, and as they are exploited, they are gradually depleting. Each year over 85% of mined phosphate rock is used in agriculture as a fertiliser for crops or as an additive to animal feed. Organic amendments can provide a sustainable alternative to traditional inorganic fertilisers, however the concentration of phosphorus in organic amendments is variable and its availability when applied to soils is relatively unknown. Knowledge of their P availability can reduce reliance on inorganic fertilisers in agriculture. Currently the most common and widely used soil tests to measure soil P are extraction techniques (e.g. Olsen-P); however the P measured by such techniques may not reflect P in a readily available form. The Diffusive Gradients in Thin-films (DGT) technique is an alternative P test which can measure the form of P available to the plant. If the DGT technique can improve understanding of soil P dynamics following application of organic amendments, it can be used as a tool to make phosphorus use in agriculture more sustainable. The objectives of the current study are as follows (1) To quantify available P pools in soil associated with application of superphosphate (SP) and different organic amendments (cattle slurry(SLRY), cattle manure (FYM) and green waste compost(GW)) and estimate the timescale required to make P available. (2) To quantify soil response to added P in relation to different application rates (0, 80, 120 kg/ha P) of the various organic amendments. (3) To measure microbial biomass P by conventional means, using DGT.

S05.01a -4

ENVIRONMENTAL IMPACT OF USING ORGANIC FERTILIZERS ON PERENNIAL BIOMASS CROPS

Cambouris Athyna^{*[1]}, Noura Ziadi^[1], Gilles Bélanger^[1], Gaétan Parent^[2]

^[1]Agriculture and Agri-Food Canada ~ Research ~ Quebec ~ Canada ^[2]Agriculture and Agri-Food Canada ~ Agri-Environment Service Branch ~ Quebec ~ Canada

Perennial herbaceous crops are considered to be the future of the bioenergy industry. Our objective was to evaluate the environmental impact of using inexpensive and widely available organic fertilizers on perennial crops for the production of biomass on marginal land. Two species were established in 2008 [switchgrass (*Panicum virgatum* L.) and reed canarygrass (*Phalaris arundinacea* L.)] as main plots of a split-plot experimental design. Fertilizer treatments as sub-plots were a factorial combination of three N sources [(ammonium nitrate (AN), pig manure (PM), and municipal biosolid (MB))] applied in spring of 2009 at three N rates (40, 80, and 120 kg total N ha⁻¹) plus a control treatment with no N. Lysimeters (0.60-m depth) were installed in four treatments (control, and each N source at 120 kg N ha⁻¹) before the application of organic and mineral fertilizers and remained in place during the entire growing season. Soil water was sampled from the lysimeters every two weeks to determine NO₃-N concentrations. Soil was sampled (0-0.6 m) on each plot immediately after crop harvesting to measure residual soil nitrates (RSN). At the end of the first production year, RSN were 67 kg NO₃-N ha⁻¹ with no significant difference between N sources or N rates. Soil water nitrate concentrations with switchgrass were always greater (4.0 vs. 1.9 mg NO₃-N L⁻¹) than with reed canarygrass with no effect of N sources or rates. No negative environmental impact of the use of PM or MB was observed after one year of production.

S05.01a -5

LONG TERM EFFECT OF COMPOST AMENDMENT IN COMMERCIAL PEACH ORCHARD: EFFECT ON SOIL FERTILITY AND TREE, NUTRITIONAL STATUS

Baldi Elena^[1], Toselli Moreno^[1], Marcolini Graziella^[1], Quartieri Maurizio^[1], Sorrenti Giovambattista^[1], Marangoni Bruno^[1], Cirillo Elio^[2]

^[1]Università di Bologna ~ Dipartimento di Colture Arboree ~ Bologna ~ Italy ^[2]Univeristà di Bologna ~ Dipartimento di Scienze e Tecnologie agrarie ~ Bologna ~ Italy

The objectives of the present experiment were to evaluate, in the long term (12 years), the effect of organic fertilization on soil fertility and tree nutrition in a commercial orchard of Stark RedGold. Trees were subjected, since their plantation, to the following treatments: 1. unfertilized control, 2. mineral fertilization including P and K applied at planting and N split in two applications at 40 days after full bloom (60%) and in September (40%) and repeated yearly; 3. cow manure supplied at planting at 10 t ha⁻¹ and from the 4th year at the rate of 5 t dw ha⁻¹ per year in spring; 4. compost supplied at the same rate of cow manure; 5. compost supplied at a rate of 5 t dw ha⁻¹ year⁻¹, and 10 t dw ha⁻¹ year⁻¹(6), both split as for treatment 2. With few exceptions, nitrate and ammonium-N soil concentrations were unaffected by treatments. Microbial C, total N and soil organic matter were increased by application of compost at high rate. With some exceptions, leaf nutrient concentrations were not affected by treatments. Cumulative yield increased as a consequence of high rate of compost if compared with unfertilized control. Unlike thinned fruits, naturally abscised leaves and pruning wood from mineral and high compost plots had a higher nutrient concentrations than the other treatments. These results indicate that yearly application of compost at 10 t ha⁻¹ does not increase the risk of nitrate pollution, instead it promotes a tree growth and production similar to mineral fertilization.

RESIDUE CHEMISTRIES OF SOLE AND MIXED ORGANIC AMENDMENTS AND THEIR EFFECTS ON SOIL MICROBIAL ACTIVITIES AND BIOCHEMICAL PROPERTIES

Partey Samuel¹

^[1]University of Manchester ~ Faculty of Life Sciences ~ Manchester ~ United Kingdom

*While there is significant evidence that the addition of organic residues to soils can improve overall soil fertility, it is unclear as to what organic residues will have the most beneficial impact. The use of residue chemistry as an index for assessing organic resource quality is highly reported and has been linked to organic matter decomposition and nutrient release patterns. However, less is reported on the direct linkages between organic residue chemistry and soil biogeochemistry and how the impact varies between sole and mixed organic residues. In this research, we investigated the residue chemistries of *Tithonia diversifolia*, *Vicia faba* and *Zea mays* (either applied alone or in combination) and how they affected and related to soil microbial activities and biochemical properties. The results revealed significant differences in chemical composition among the species and affirmed that organic materials impact differently on soil microbial and biochemical properties based on their chemistry. Carbon, polyphenol, C: P and lignin: N ratios had the greatest impact on soil microbial activities and biochemical properties. The levels of biological activities were comparable in sole and mixed amendments but N mineralization and availability increased significantly in *V. faba* and *T. diversifolia* amendments. The results also demonstrated that basal respiration, microbial biomass carbon and the activities of β -glucosidase and β -glucosaminidase are sensitive indicators of nitrogen availability and organic C levels in soils.*

NITROGEN FERTILIZER REPLACEMENT VALUE OF HEAT-DRIED MUNICIPAL BIOSOLIDS

Sullivan Dan M.*^[1]

^[1] Oregon State University ~ Crop & Soil Science ~ Corvallis ~ United States

*Municipal wastewater treatment facilities in the Pacific Northwest, USA have been upgraded to produce heat-dried biosolids, instead of dewatered or slurry biosolids. Heat-dried biosolids have greater value to farmers and urban markets because they can be pelleted, stored, transported, bagged and used by consumers with traditional fertilizer spreading equipment. Several researchers have recently reported very high nitrogen (N) availability from heat-dried biosolids (> 60% of total N). Our research evaluated the N fertilizer replacement value of heat-dried biosolids produced by an Andritz dryer (operating at inlet temp of 455 to 480 C) relative to a standard inorganic N fertilizer (urea; 46-0-0) in three field trials (2009-11). The test crop was rain-fed soft-white winter wheat (*Triticum aestivum*) seeded in fall and harvested the following summer. Biosolids were broadcast on the soil surface in fall at seeding, or in early spring at tillering growth stage at Corvallis, OR USA (Oct-Mar precip > 700 mm). Urea was applied in spring only (standard agronomic practice). Trials were conducted at new field locations in each year. Nitrogen fertilizer replacement value of biosolids averaged 35% with fall application, and 45% with spring application, as determined by relative grain N uptake for biosolids vs. urea treatments. We conclude that N fertilizer replacement value for heat-dried biosolids was close to that estimated by our current university guidance for air-dried biosolids (30 to 40% of biosolids total N in first year after application).*

**RELATIONSHIPS BETWEEN GREEN WASTE COMPOST APPLICATION TO ARABLE SOILS
AND NITROUS OXIDE EMISSIONS**

Watson Kirsty^[1], Sakrabani Ruben^[1], Ritz Karl^[1]

^[1]Cranfield University ~ School of Applied Sciences ~ Bedford ~ United Kingdom

Rising global population paired with increasing environmental awareness has put pressure on the agricultural sector to increase yield whilst maintaining or reducing its environmental footprint. It is estimated that within the UK, agriculture contributes 66% of all N₂O emissions, with around 61% of this resulting from soil emissions. Furthermore the increasing costs of ammonium nitrate is forcing the re-examination of more traditional organic fertilisers, however, the unpredictable nature of the quantity and timing of nitrogen release acts as a barrier to their widespread commercial adoption. Therefore it is necessary to look at impact of green waste compost (GWC) and inorganic fertiliser use within the conceptual frame work of synchronising crop demand with N supply in order to maximise N use efficiency and thereby reduce N losses. Field trials were established at 2 sites: Elveden, Suffolk (established in 2010) and Morley, Norfolk (established in 2007). Trials consisted of 2 treatments, inorganic fertiliser and inorganic fertiliser and GWC (35t/ha) with treatment plots of 6m x 12m, with four replicates. Both sites were planted with cereal crops; spring barley and winter wheat respectively. The Morley site demonstrated a clear treatment effect with compost amended plots exhibiting significantly lower (p-value < 0.0000) N₂O emissions than the control plots with emissions of 157 and 249 gN₂O-N ha⁻¹ d⁻¹ respectively. However this treatment effect was not evident at the Elveden field site, implying a relationship with GWC application duration. The anomalous weather conditions during the 2010/2011 growing season are likely to have influenced results.

S05.01b -3

ANIMAL MANURE APPLICATION AND SOIL C STORAGE: A GLOBAL META-ANALYSIS

Angers Denis^[1], Maillard Emilie^[1]

^[1]Agriculture and Agri-Food Canada ~ Soils and Crops Research centre ~ Québec ~ Canada

The positive effect of animal manure application on soil organic C (SOC) has been known for centuries. However, there is a large variability in the response of soils to manure application, and environmental factors and manure characteristics controlling this response are still poorly defined. Improving the quantification and understanding the variability of this response will contribute to select management practices, improve national SOC inventories and validate SOC models. This study provides a review of the influence of animal manure application on SOC stocks based on a meta-analysis of 64 publications (totalling 71 sites and 242 observations). Based on meta-analytic procedures, the study indicates that the main factors that contribute to increasing SOC stocks following manure application are: land use, animal origin, manure storage method, and climatic zone. Specifically, the analysis (1) indicates that the positive impact of manure application on SOC stocks is more pronounced in perennial than annual cropping systems; (2) suggests that cattle manure leads to greater SOC accumulation than pig; (3) underscores that solid results in greater SOC stocks than liquid manure; (4) suggests that manure application carried out in the oceanic and humid continental climate zones results in larger SOC accumulation than in humid subtropical climate. This study provides meta-analytic data that can be used to refine the C change factors for national greenhouse gas inventories provided by IPCC for manure management.

ORGANIC C BALANCE AND DYNAMIC OF MICROBIAL POPULATIONS IN A SOIL AMENDED WITH LIVESTOCK-DERIVED ORGANIC MATERIALS

Pezzolla Daniela^{*[1]}, Turchetti Benedetta^[2], Buzzini Pietro^[2], Albertini Emidio^[2], Agnelli Alberto^[1], Gigliotti Giovanni^[1]

^[1]University of Perugia ~ Department of Agricultural and Environmental Sciences ~ Perugia ~ Italy ^[2]University of Perugia ~ Department of Applied Biology ~ Perugia ~ Italy

The increase of CO₂ emissions is currently considered the most relevant issue causing the climatic changes. The balance of organic C into the soil is affected by of inputs and outputs and the amendment of agricultural soils by livestock-derived organic materials (LD-OM) is one of the tools for increasing input of organic C. Soil amendment can affect soil microbial activity, in terms of consistence of microbial biomass and in terms of both prokaryotic and eukaryotic microbial diversity. The results about the C balance and microbial activity in the soil amended with LD-OM are herein reported. When compared with an undisturbed soil (US), the addition of LD-OM determined an early increased CO₂ emission (first 10 days), which resulted in lower release afterwards, as well as the amount of water soluble organic matter, which is the most easily degradable by microorganisms. LD-OM amended soil exhibits a low amount of soluble organic matter than US, whereas microbial biomass was higher in US. The level of culturable prokaryotic and eukaryotic microbiota in amended soil was higher in the early phases for yeasts and filamentous fungi, whereas bacterial flora substantially unchanged. The unculturable portion of both prokaryotic and eukaryotic microbial populations have also been evaluated. Moreover, a next generation sequencing approach was employed. Total microbial DNA was isolated from 8 soil samples (control and amended) and subjected to 454 sequencing with the aim of monitoring the changes in microbial community structure due to amendants. Results are under statistical evaluation and will be presented and discussed.

S05.01b -5

MICROBIAL EXTRACELLULAR POLYMERIC SUBSTANCES (EPS) IN SOIL

Redmile-Gordon Marc^{*[2]}

^[1]Rothamsted Research ~ Sustainable soils and grassland systems ~ London ~ United Kingdom

Many benefits of amendments to soil are due to by-products such as exocellular proteins and polysaccharides (EPS) exuded by the microbial biomass during the breakdown of labile organics. EPS are known to convey improved colony adhesion, habitat heterogeneity, and biochemical function to soil biota. This is thought to benefit soil characteristics, e.g. structure, nutrient cycling, and contaminant immobilisation. Moreover, EPS provides desiccation tolerance, which is expected to improve water-use-efficiency and extend periods of agricultural productivity. To assess these impacts, a method to quantify EPS is required. Existing methods of extraction from soil co-extract intra-cellular materials and humified organic matter. Here we compare several techniques to extract EPS from soils of two contrasting managements (grassland and bare fallow), with and without 2mg glycerol carbon addition g⁻¹ soil. Extractions included autoclaving with 20mM citrate or 0.5M H₂SO₄ and a cold extraction with cation exchange resin (CER). Changes in cellular ATP were used as an indicator of cell-lysis (Redmile-Gordon et al., 2011). Extracting with CER did not affect microbial ATP, and extracted the greatest proportion of sugars developed in response to glycerol substrate. This extract is thus thought to be most representative of de-novo exocellular polysaccharides of microbial origin. Quantifying this fraction is important to distinguish between the relative contributions of organic amendments and microbial products to soil characteristics. Further work with stable isotopes is underway to identify amino acids and monosaccharides constituting de-novo EPS developed from a variety of substrate additions to soil.

S05.01b -6

BIOCHAR : A HUMIC PRECURSOR

Hayes Michael H.B. ^{*[1]}

^[1]University of Limerick ~ Carbolea Research Group ~ Chemical and Environmental Sciences ~ Limerick ~ Ireland

The extraordinary fertility of the Terra Preta soils, amended by pre-Columbian Indians of the Amazon Region with pyrolysed organic refuse and biomass, has focused world-wide interest on the potential of biochar (or char from biomass) to enhance plant growth and promote the proliferation of beneficial soil organisms. Many recent studies have shown the presence of biochar in highly fertile soils. The dark colour of the Mollisol soils (the source of the IHSS soil standard) of the Midwestern US is attributable to char from burning vegetation in centuries past. The aromatic resonance in the NMR spectra of the humic and fulvic acids of these soils is characteristic of biochar, and resin technology has isolated a partially oxidised biochar from more recently formed humic substances. Because of its role in soil fertility and in carbon sequestration, biochar has the potential to become an important commercial product. It is inevitable that the industry will be regulated. Our studies show that the desirable properties of biochar are related to the source material, to the temperature and time of pyrolysis, and to the soil that it amends. Retention of aspects of the plant cell architecture is important. Biochar from lignocellulosic biomass is non mutagenic, but pyrolysis of proteinaceous and other materials gives mutagens. Highly beneficial Arbuscular Mycorrhizal fungi (AMF) that enable plant uptake of fixed phosphate, and Azospirillum (nitrogen fixing) species colonize porous biochars.

S05.01c - SOIL ORGANIC MATTER AMENDMENTS: IMPACTS, BENEFITS, AND RISKS

^[1]Nova Scotia Agricultural College ~ Environmental Sciences ~ Truro ~ Canada ^[2]Nova Scotia Agricultural College ~ Plant and Animal Sciences ~ Truro ~ Canada

The impact of green manures and biowaste composts on soil quality were evaluated in a potato rotation during 2008 and 2010. The preceding crops were (G1) oats underseeded with red clover (ORC)-carrots-ORC-red clover (RC); (G2) beans followed by buckwheat (BBu)-carrots-ORC-RC; (G3) ORC-BBu-carrots-oats/pea/vetch mixture (OPV); and (G4) ORC-carrots-BBu-OPV. Fertility treatments (applied only in the potato year) included: non-amended (control), municipal food waste compost (MSFW; 7 Mg DM ha⁻¹), composted paper mill biosolids (PMB; 14 Mg DM ha⁻¹) or P and N synthetic fertilizers (FERT) used for reference. Soil quality indicators were measured in the top 15 cm of the potato hill at the tuber initiation stage and averaged across years. The amount of carbon (C) that added to the soil was 4.1 and 2.7 Mg ha⁻¹ for RC and OPV, and 3.3 and 1.1 Mg ha⁻¹ for PMB and MSFW, respectively. Soil quality parameters were not affected by crops rotation except for total organic C (TOC) which highest levels were measured for the RC+PMB compared with other treatments (43 vs. 32 Mg ha⁻¹). Highest amounts of particulate organic matter (POM)-C were measured for PMB (8.6 Mg ha⁻¹) followed by MSFW, FERT and control. The total organic N (TON) and POM-N were highest for MSFW~PMB (6.2 and 0.80 Mg ha⁻¹) followed by FERT and control. Highest and lowest microbial quotient values were measured for MSFW and PMB, respectively (0.71 vs. 0.45%). Microbial biomass C and acid phosphatase activity were not affected by biowaste treatment. Green manure maintained while compost improved soil quality.

In order to remediate soil pollution, different techniques have been developed in the last decades. However, such techniques may have negative effects on soil physical, chemical and biological properties, and affect soil fertility and biological activity. Post-treatment soil construction using wastes and by-products may provide means to restore primary functions of the soil. The "OXYSOL" project aimed to develop in situ chemical oxidation of PAH contaminated soils combined with a post-treatment restoration of soil properties. Microcosm and lysimeter experiments were performed with different soils treated by chemical oxidation and amended with adapted mixtures of technogenic materials. The microcosm experiment was set up for 5 months in a growth chamber with a PAH spiked soil and an industrial PAH contaminated soil, both treated with Fenton's reaction, then amended or not with a mixture of paper mill sludge and compost. Beside the fate of pollutants, the following parameters were monitored: microbial density, diversity and activity, soil fertility, ecotoxicity and plant germination and growth. The results showed different responses after chemical oxidation treatment depending on soil characteristics. Parameters like pH, microorganism's density, enzymatic activity, organic carbon, available phosphorus were affected, and leachate toxicity was observed. The strong pH decrease for the spiked soil lead to unfavourable conditions for biological activity. Following the addition of post-chemical-treatment amendments the capacity of plants to grow on the treated soils was restored and there was a systematic increase of biological activity.

BIOCHAR APPLICATION IN TEMPERATE SOILS: LESSONS LEARNED FROM FIELD AND LAB

Schimmelpfennig Sonja*^[1], Kammann Claudia^[1]

^[1]Justus-Liebig-University ~ Experimental plant ecology ~ Giessen ~ Germany

We incubated grassland soil (Clay loam, pH 5,8) with three different substrates: untreated miscanthus (feedstock), hydrothermal carbonized miscanthus (hydrochar) and pyrolyzed miscanthus (biochar). The addition of the substrates was carried out with respect to the TOC-content of the soil (3%), which has been increased by 20% with the help of the substrates. To simulate real grassland conditions, we added slurry as fertilizer twice during the experimental period. Greenhouse gas fluxes (CO₂, N₂O und CH₄) have been measured on a weekly basis since initiation of the experiment. It could be shown that with feedstock and biochar, CO₂ emissions increased significantly, whereas addition of biochar did not influence CO₂ fluxes. Gas sampling was complemented by isotope analyses to determine the source (soil/additive) of the oxidized carbon. Concerning N₂O and CH₄-emissions, the addition of hydrochar and biochar led to a significant reduction in N₂O emissions, whereas all substrates increased the methane oxidation potential of the soil. The experiment was complemented by CEC and Nmin analyses combined with evaluation of the growth performance of Lolium perenne. These results from the incubation study were compared with first results from a biochar field trial on a grassland site near Giessen with similar parameters. Weekly greenhouse gas measurements were accompanied by isotopic measurements to determine long term biochar stability. We compare changes in biomass growth and species composition with ecosystem respiration and try to identify changes in soil parameters due to biochar amendments by means of TOC, Nmin content and aggregate structure analyses.

^[1]Fondazione Edmund Mach ~ FoxLab ~ San Michele all'Adige (TN) ~ Italy ^[2]Fondazione Edmund Mach ~ CRI-Research and Innovation Centre ~ San Michele all'Adige (TN) ~ Italy ^[3]Ibimet-Cnr ~ Ibimet-CNR ~ Bologna ~ Italy

*Biochar, a charcoal used as a soil amendment, is reported to increase crop yields. However, mechanisms behind this effect are not yet fully understood. Recent studies showed that biochar increases the production of ethylene (C₂H₄), a phytohormone, suggesting an ethylene-mediated mechanism by which biomass yields are increased. In order to verify this observation a pot experiment was performed with *Arabidopsis thaliana* ecotype Col-0, which shows elongation and early germination in the presence of ethylene, and the *etr1-3* mutant, which is insensitive to ethylene. Seeds were sown in sealed jars in a soil amended with 0, 5 and 10% of biochar. After 15 days we observed hypocotyl and petiole elongation and earlier plant germination in the wild-type compared to the ethylene insensitive mutant. The difference between the mutant *etr1-3* and its wild type was more evident at higher biochar concentrations, suggesting that ethylene production is due to biochar. These observations have been verified and confirmed through ethylene assessment with a GC fitted with a FID detector. This presentation will illustrate the key results of our study, discussing how ethylene effects might eventually translate into potential benefits in field application of biochar.*

BIOCHAR CARBON SEQUESTRATION: THE EFFECTS OF FEEDSTOCK AND TEMPERATURE OF PYROLYSIS ON CHEMICAL AND PHYSICAL STABILITY

Rao Meghana*^[3]

^[1]Oregon State University ~ Soil Science ~ Beaverton, Oregon ~ United States ^[2]Jesuit High School ~ Sophomore ~ Portland ~ United States ^[3]Jesuit High School ~ Crop and Soil Research ~ Portland ~ United States

This novel research studied effects of feedstock and temperature of pyrolysis on chemical and physical stability of biochar. Biochar, carbon-rich charcoal soil amendment, is a potential carbon-negative solution to reduce atmospheric carbon. Biochar stores 50% of the of the plant's carbon dioxide in carbon sinks with a predicted half-life of millenniums. Long-term stability is currently undetermined. Biochar was made in a Top-lit Updraft (TLUD) stove (360-420°C) and Fluidyne Pacific Class Gasifier (above 420°C) using Douglas fir chips, Hydrostraw (grass), and methane digester pellets. Proximate analysis determined moisture, volatile matter, and ash content. Chars were ultrasonicated, simulating physical stress over centuries. A Total Organic Carbon Analyzer measured lost carbon and nitrogen. Chemical stability was determined by mass lost through oxidation. The stability of carbon in grass and pellet chars increased with temperature; wood char decreased. After ultrasonication, TLUD pellet char lost 1.68% initial total carbon (TC), the highest across all chars, and .44% total nitrogen (TN). Wood 550°C lost the least TC (.01%) and .3% TN. Wood was the most carbon stable, then grass and pellets. The physical and chemical stability did not correlate. Wood 550C lost 80% mass after chemical oxidation. Grass lost the least mass (avg 17%), then pellets (avg 23%), lastly wood (avg 56%). The results demonstrate feedstock and temperature of pyrolysis affect the stability of biochar. Extended research is currently being done on the effect of particle size on stability, determining a rate of oxidation, and effects of freezing and thawing as a function of water-accessible volume.

S05.01c -6

BIOCHAR – A POSSIBLE SOURCE OF ORGANIC POLLUTANTS?

Wiedner Katja*^[1], Glaser Bruno^[1]

^[1]Martin-Luther-University Halle-Wittenberg ~ Soil Biogeochemistry ~ Halle ~ Germany

Besides the positive effects of biochar in soils, biochar could be also an undesirable source of toxic substances like polycyclic aromatic hydrocarbons (PAHs) and polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs). Due to the persistence and toxicity, it is of great importance to obtain a good understanding of their sources such as feedstocks or production processes. For this purpose, we determined the PAHs, PCDDs and PCDFs as well as general chemical properties (elemental composition, pH, electric conductivity, black carbon and ash content) of diverse biochars and hydrochars produced from different feedstocks and production processes. Our study showed the following results: the total EPA-PAH amounts of all tested biochars ranges between 0.1 and 1.4 mg PAH kg⁻¹. The PCDD/Fs contents of the biochars and hydrochars vary from 5.95 to 14.2 ng/kg. The amounts are also under the boundary value adjusted to the german sewage sludge ordinance. In contrast, the concentrations of PAHs in the hydrochars vary strongly from 0.5 to 12 mg PAH kg⁻¹. According the German Bundes-Bodenschutzverordnung (BBodSchV), critical precautionary values for soils with a humus content > 8% and ≤ 8% are 10 and 3 mg PAH kg⁻¹ (dry mass), respectively. Following the BBodSchV, PAH threshold values of some examined hydrochars were exceeded. The results indicate the great importance to specify a legal framework for biochar as soil amendment. Therefore, more research is needed concerning the formation of organic pollutants with respect to biochar production before adding it into agricultural used areas.

S05.01c -7

USING A MULIVARIATE APPROACH TO DERIVE A GENERALISED UNDERSTANDING TO PREDICT THE FUNCTIONS OF BIOCHAR IN SOIL

Sohi Saran^{*[1]}, Cross Andrew^[1], Peters Clare^[1]

^[1]UK Biochar Research Centre ~ School of GeoScience ~ Edinburgh ~ United Kingdom

Various trends in certain features of biochar have been reported when comparing systematic sets of material produced by a single set of equipment. However, a generalised, predictive understanding of how feedstock and biomass conversion parameters will determine the function of biochar products in soil, in terms of carbon storage, nutrient and water cycling and, ultimately, crop performance or yield, is lacking. This compromised the ability to demonstrate the extent and limits of its utility in soil management. To address this critical gap we developed a set of novel laboratory assays and applied them to more than 30 samples of biochar. None of the biochar samples were selected such that no sample had more than one production parameter in common with more than one other sample, each sample was from a different facility and encompassed a complete range of processes. The assays seek to provide a comprehensive, comparative assessment of five key functions of biochar in soil, seeking to mimic the behaviour of biochar in the field environment over periods of time relevant to each function. Multivariate statistical analysis was applied to the results, firstly to assess the level of co-correlation between the functional properties that were assessed across the sample set, secondly to examine the relative contributions to total variance for each assay and overall, attributable to feedstock type certain process settings affecting the products of pyrolysis. Results from this analysis will be presented together with an assessment of its utility and suggestions for targeting further work.

IMPACTS OF SOIL AMENDMENTS ON FATE AND BEHAVIOR OF POLLUTANTS IN SOIL

Kreuzig Robert^[1]

^[1]Technische Universität Braunschweig ~ Institute of Environmental and Sustainable Chemistry ~ Braunschweig ~ Germany

In agricultural production, soil amendments are used to improve soil quality. Besides mineral fertilizers or green manures, sewage sludges, liquid manures and liquid fermentation wastes are applied as organic fertilizers due to their contents of organic matter and plant nutrients. Furthermore, the effect of biochar amendment is studied for biosequestration or atmospheric carbon storage. Finally, cross-linked polyacrylates are applied as superabsorbent polymers to absorb plant available water and thus to particularly optimize irrigation systems in aride regions. Besides benefits, environmental risks are to be taken into consideration as well. Thus, sludges and manures may be contaminated either by heavy metals and persistent organic pollutants. Superabsorbent polymers are furthermore well-known as a persistent material able to absorb heavy metals and salts to counteract heavy metal and salt stress of plants. However, the impact of those soil amendments on fate and behavior of inorganic and organic soil pollutants and on the microbial community in soil is rather disregarded or completely unknown until today. In order to close this gap in knowledge, advanced test systems have to be designed, particularly when risk assessment of regulatory procedures, e.g., for pharmaceuticals or biocides, is based exclusively on laboratory testing.

^[1]Universität Trier ~ Bodenkunde ~ Trier ~ Germany ^[2]Forschungszentrum Jülich ~ IBG-3 ~ Jülich ~ Germany ^[3]CRP-Henri Tudor ~ CRTE ~ Luxembourg ~ Luxembourg ^[4]Universität Rostock ~ IfL - Bodenkunde ~ Rostock ~ Germany

Pharmaceutical antibiotics reach arable soil as contaminants of manure used as agricultural fertilizer. Manure was previously shown to affect the sorption and mobility of antibiotics in soil. However, manure or slurry are extremely heterogeneous matrices, varying with live stage of animals, feeding and manure collection management of the farm. The different manure composition has strong implications on the fate of xenobiotics in soil. To follow up this heterogeneity, pig slurry from different farms and animal live stages was analysed. To this end, physical size fractionation of slurry samples was done and general physicochemical parameters such as total OC and N, DOC and DON etc. were determined. On top of that a more in-depth investigation of the chemical composition of slurry was performed using (i) pyrolysis-field ionisation mass spectrometry (Py-FIMS) of manure fractions and (ii) high resolution Fourier transform ion cyclotron resonance (ESI-FT-ICR-MS) for the analysis of manure fractions leaching from soil columns. The analyses revealed that the chemical composition differs between manure particle size fractions that are differently prone to transport in soil. Also, manure composition itself is altered upon soil transport. Combined with soil column experiments on transport of antibiotics from different structural classes, these data show the interaction between solute, soil and manure properties on the transport of antibiotics in soil.

S05.02 -3

PHYSICOCHEMICAL AND SORPTION PROPERTIES OF THERMALLY-TREATED SEDIMENTS WITH HIGH ORGANIC MATTER CONTENT

Bo Pan*^[1]

^[1]Kunming University of Science & Technology ~ Faculty of Environmental Science & Engineering ~ Kunming ~ China

Sediment samples with high organic carbon contents (22.04% and 8.46%) were collected and thermally treated using a method analogous to biochar production. The obtained thermally-treated sediments (TTSs) showed a much higher degree of carbon capture in comparison to biochar derived from common biomass, indicating potential use of TTSs in soil amendment and carbon sequestration. Their sorption with organic contaminants was also investigated using sulfamethoxazole (SMX) as a model sorbate. SMX sorption increased greatly with pyrolytic temperature. Desorption ratio of the adsorbed SMX in TTSs generally decreased with increased pyrolytic temperature and with decreased solid-phase concentrations. The thermodynamic analysis showed that the higher entropy increase (positive ΔS) was well related with the decreased desorption ratio with increased solid-phase concentration for the original sediments. The fate-controlling effect of contaminants in TTS application for soil amendment should be evaluated combining sorption/desorption and sorption thermodynamic studies.

EFFECT OF BIOCHAR PROPERTIES AND WEATHERING ON SORPTION OF THE SWINE ANTIBIOTIC SULFAMETHAZINE IN BIOCHAR-AMENDED SOILS

Pignatello Joseph^{*[1]}, Teixido Marc^[2], Beltran Jose L.^[2], Granados Merce^[2]

^[1]Connecticut Agricultural Experiment Station ~ Environmental Sciences ~ New Haven ~ United States ^[2]Universitat de Barcelona ~ Departament de Química Analítica ~ Barcelona ~ Spain

The widespread use of veterinary antibiotics results in contamination of soil via grazing and manure application, leading to concern about antibiotic resistance transfer to pathogens in soil. Biochar—a form of black carbon derived from biomass waste pyrolysis—has attracted interest as a beneficial soil amendment. Since black carbon can be a potent adsorbent of organic compounds, we postulated that biochar addition would reduce bioavailability of antibiotics through enhanced adsorption. To test this, we studied adsorption of the heavily used sulfonamide antibiotic, sulfamethazine (SMT), to soils amended with different commercial biochar prototypes at levels of 1 or 2% by weight. The biochar-water distribution coefficient (K_{bc}) of SMT ranged as low as 10^1 to as high as 10^6 L/kg, depending on SMT concentration and the biochar source. By comparison, the octanol-water partition coefficient K_{ow} is $10^{0.27}$, and the organic carbon-water partition coefficient K_{oc} for the soil tested is $10^{1.4}$. The K_{bc} trended with percent C, C/H mole ratio, N₂ B.E.T. surface area, CO₂ micropore surface area, and CO₂ microporosity. Sorption to the soil-biochar mixture increased in most cases in relation to the biochar amendment rate and the K_{bc} . Pre-equilibration (weathering) of soil-biochar-water mixtures for 28 d prior to SMT addition suppressed sorption relative to the non-weathered mixture by up to an order of magnitude due to biochar pore blockage by soil humic substances. This work demonstrates the potential for biochar to reduce bioavailability of antibiotics in soil but illustrates the important effect of attenuation that occurs with weathering.

S05.02 -5

THE USE OF BIOCHAR TO MINIMIZE THE BIOAVAILABILITY OF POLYCHLORINATED BIPHENYLS (PCBS) AT CANADIAN BROWNFIELD SITES

Denyes Mackenzie^{*[1]}, Zeeb Barbara^[1], Rutter Allison^[2]

^[1]The Royal Military College of Canada ~ Chemistry and Chemical Engineering ~ Kingston ~ Canada ^[2]Queen's University ~ School of Environmental Science ~ Kingston ~ Canada

*Biochar is a carbon rich by-product produced from the pyrolysis of organic matter. In recent years, studies have focused on the potential to use activated carbon to sorb organic pollutants in sediments and soils. However, little data exists on the potential of using biochar, which as a consequence of its production, is a greener and more cost effective material than activated carbon. A greenhouse experiment, carried out in two levels (136 µg/g and 3.1 µg/g) of polychlorinated biphenyl (PCB)-contaminated soil, indicated that biochar added at 2.8% (w/w) to soil reduced shoot and root concentration in the known phytoextractor *Curcubita pepo* ssp. *pepo* (pumpkin) by up to 23% and 77%, respectively. Biochar also reduced the PCB concentration in *Eisenia fetida* (redworm) tissue by 52%. A subsequent field scale study was conducted at a Canadian Brownfield site (i.e. an abandoned industrial facility) contaminated with >50 µg/g PCBs using two different types of biochar added at 2.8% (w/w). In this same trial granulated activated carbon (GAC) was added at 2.8% (w/w) to serve as a positive control and assess the efficiency of biochar to sorb PCBs. Preliminary results show that biochar amendments improved soil quality, increased harvestable plant wet weights, and decreased the bioavailability of PCBs to both *C. pepo* and *E. fetida* at rates comparable to GAC. Thus, biochar has potential to serve as an amendment to decrease the bioavailability of PCBs in the soil, and may have potential to be used in Brownfield remediation strategies.*

S05.02 -6

INFLUENCE OF SEWAGE SLUDGE TREATMENT AND APPLICATION TO AN ACID AND A NEUTRAL SOIL ON THE GROWTH AND METAL UPTAKE OF BRASSICA NAPUS

Contin Marco^[3], Izosimova Alexandra^[2], De Nobili Maria^[3]

^[1]UNIVERSITY OF UDINE ~ DEPARTMENT OF AGRICULTURE AND ENVIRONMENTAL SCIENCES ~ UDINE ~ Italy

^[2]Agrophysical Research Institute ~ Department of field experiments and chemical land reclamation ~ Saint-Petersburg ~ Russian Federation ^[3]University of Udine ~ Department of Agriculture and Environmental Sciences ~ Udine ~ Italy

The use of sewage sludge in agriculture is an attractive alternative disposal technique as this waste is rich in organic C as well as macro- and micro-nutrients. However, its application can cause accumulation of toxic elements in soil and their transfer to plants and animals. The addition of FeCl₃ as coagulant for P removal, can result in the precipitation of Fe (hydr)oxides that are known to be strong metals adsorbents, but could interfere with organic matter mineralization and affect nutrient release. The aim of our study was to quantify the effect of FeCl₃ treatment of sewage sludge on growth and accumulation of potentially toxic elements of plants. Brassica napus was cultivated in pots for 50 days on an acid soil (pH 4.5) and on a calcareous soil (pH 7.8) added with 25 g kg⁻¹ native sewage sludge and sewage sludge treated with FeCl₃ as coagulant. The influence of sludge application on dry matter accumulation of Brassica napus was described with logistic functions. Both types of sludge improved dry matter accumulation significantly. Sludge coagulation with Fe did not affect plant growth in both soils, but in the acid soil its application enhanced the accumulation of Zn, Cd, Mn and Ni in plants. On the opposite, in the neutral soil this effect was not observed with the exception of Cd, which was higher in plants treated with Fe coagulated sludge on the 20-30 days of growth; this difference disappeared thereafter. Iron uptake was unexpectedly not influenced by sludge treatments.

S05.02 -7

IMPACTS OF SOIL AMENDED SUPERABSORBENT POLYMERS ON THE EFFICIENCY OF IRRIGATION MEASURES IN JORDANIAN AGRICULTURE

Al Tarawneh Amjad^[1], Kreuzig Robert^[1], Bahadir Müfit^[1], Batarseh Mufeed^[2]

^[1]Technische Universität Braunschweig ~ Institute of Environmental and Sustainable Chemistry ~ Braunschweig ~ Germany ^[2]Mutah University ~ Prince Faisal Center for Dead Sea, Environmental and Energy Research ~ Karak ~ Jordan

Water scarcity is the most important natural constraint to Jordan socio-economic development and has particularly negative impacts on the agricultural production due to proceeding desertification. Therefore, the Jordanian water strategy emphasized the use of reclaimed water to replace third amount of fresh water currently used for irrigation measures. Additionally, the irrigation efficiency in sandy soil can be enhanced by the application of superabsorbent polymers. These highly cross-linked potassium-polyacrylates increase the water holding capacity of soil by absorbing plant available water. The sorption of inorganic pollutants may furthermore contribute to reduce heavy metal and salt stress to plants. Hence, this study performed within the DAAD funded Exceed Project "Sustainable Water Management in Developing Countries" aims to investigate the simultaneous application of reclaimed irrigation water and superabsorbent polymers in test-field scale. For this purpose, eggplants are cultivated in sandy soil amended by 0, 0.2 and 0.4 % of superabsorbent polymers and irrigated using fresh and reclaimed water. Heavy metals as well as microorganisms are analyzed in irrigation water, soil and plants. The latter are differentiated into leaves, stems, roots and fruits and analyzed for heavy metal accumulation. During the vegetation period, growth parameters and biomass production of test plants are additionally determined. In additional pot and laboratory tests, the impacts of superabsorbent polymers on the water availability to plants and on sorption of heavy metals in soil are studied.

TIERRA NEGRA ANDALUZA – AN EXAMPLE HOW BIOCHAR APPLICATION MAY ALTER SOIL ORGANIC MATTER COMPOSITION ON A LONG TERM SCALE

Knicker Heike^{*[1]}, González Vila Francisco J.^[1], Clemente Salas Luis^[1]

^[1]IRNAS-CSIC ~ Department of Biogeochemistry ~ Sevilla ~ Spain

The “Tierra negra andaluza” represents a Vertisol which occurs frequently in the valley of the Guadalquivir, Southern Spain. In spite of their low organic C contents (< 2 %), these soils appear rather dark. Being fertile, they have been cultivated since millennia. Analysis of their soil organic matter (SOM) by solid-state ¹³C NMR spectroscopy revealed high aromatic C contents (up to 35% of total organic C). Preliminary ¹⁴C dating indicated a mean age of the SOM of approximately 5000 years. Chemical oxidation with acid potassium dichromate confirmed considerable contributions of pyrogenic organic material (PyOM), possibly incorporated into the soils as a consequence of early-time slash and burn practice. Alternatively, it may have been added stepwise by continuing after-harvest-burning of crop residues, which since ancient times was and still is a common agricultural managing form in this area. The effect of PyOM and its aging on SOM turnover in these soils is presently explored in more detail with further respiration experiments. First results confirmed slightly slower turnover rates of charcoal than of SOM. Thus, the observed high PyOM contents of the “Tierra negra” are best explained by a selective preservation of PyOM and scarce fresh litter input due to crop removal and burning of the remains. Employing our observation for an evaluation of the impact of modern biochar amendment to soil, a major concern may be a considerable aromatization of the SOM. To which extend this may alter other soil properties, however, has still to be investigated.

S05.03a -2

A META-ANALYSIS OF THE EFFECTS OF BIOCHAR APPLICATION TO SOILS ON CROP PRODUCTIVITY

Jeffery Simon^{*[1]}, Verheijen Frank^[5], Van Der Velde Marijn^[3], Bastos Ana^[4]

^[1]none ~ none ~ Laveno ~ Italy ^[2]Department of Environment and Planning ~ Centre for Environmental and Marine Studies ~ Aveiro ~ Portugal ^[3]International Institute for Applied Systems Analysis ~ One of them ~ Laxenburg ~ Austria

^[4]Centre for Environmental and Marine Studies ~ Department of Biology ~ Aveiro ~ Portugal ^[5]Centre for Environmental and Marine Studies ~ Department of Environment and Planning ~ Aveiro ~ Portugal

One of the most commonly reported agronomic benefit of adding biochar to soils is increased crop yields. However, causative mechanisms are yet to be fully elucidated and can be obscured owing to variations in experimental set-up, soil properties and conditions. Therefore, a meta-analysis was undertaken with the aim of evaluating the relationship between biochar and crop productivity (either yield or above-ground biomass). Results showed statistically significant benefit of biochar application to soils on crop productivity, with a “grand mean” calculated from the data from all of the studies included found to be an increase of 10% in crop productivity/yield. However, the mean results for each analysis performed were variable (from -28% to 39%). The largest (positive) effects with regard to soil analyses occurred in acidic (14%) and neutral soils (13%), and in soils with a coarse (10%) or medium textures (13%). It seems probable, therefore, that the main mechanisms for yield increase include improved water holding capacity of the soils, concurrent with along with improved crop nutrient availability as well as liming effects. Of the biochar feedstocks considered and in relation to crop productivity, poultry litter showed the strongest (significant) positive effect (28%), in contrast to biosolids, which were the only feedstock showing a statistically significant negative effect (-28%). However, information concerning co-variables reported in the literature were often incomplete. Furthermore, the full range environmental and management conditions in relevant soil types and over longer timeframes are yet to be investigated.

THE BIOCHAR EFFECT: PLANT GROWTH PROMOTION AND RESISTANCE TO BIOTIC STRESSES

Graber Ellen R.^{*[1]}, Elad Yigal^[2]

^[1]The Volcani Center ~ Institute of Soil, Water and Environmental Sciences ~ Bet Dagan ~ Israel ^[2]The Volcani Center ~ Institute of Phytopathology ~ Bet Dagan ~ Israel

The positive impacts of biochar on crop productivity are frequently attributed to different direct and indirect effects (e.g., biochar-supplied nutrients, increased water and nutrient retention, improvements in soil pH and CEC, promotion of mycorrhizal associations). Yet, improved crop performance is also evident under conditions of intensive production where many of these soil functions are neither limited nor relevant. Moreover, biochar has been found to induce plant systemic resistance responses against disease-causing fungi. The severity of diseases caused by Botrytis cinerea (gray mold) and Oidiopsis sicula (powdery mildew) foliar pathogens in pepper and tomato was significantly reduced in biochar-amended treatments. Reduced damage by broad mite (Polyphagotarsonemus latus) in biochar-amended pepper plants was also observed. In addition, biochar amendment resulted in suppression of Podosphaera aphanis (powdery mildew), B. cinerea and Colletotrichum acutatum (anthracnose) in strawberry. How does biochar promote plant growth and induce system-wide resistance? Biochar addition to soil alters microbial populations in the rhizosphere, and may cause a shift towards beneficial microorganism populations that promote plant growth and resistance to biotic stresses. Moreover, systemic resistance may be induced by various chemical components of the residual tars in biochars. Molecular studies in strawberry indicate that biochar induces responses along both systemic acquired resistance and induced systemic resistance pathways, resulting in a broad spectrum controlling capacity. Improvement of plant responses to disease can be one of the benefits gained from applying biochar to soil.

BIOCHAR EFFECTS ON ARID AND SEMI-ARID SOIL CHEMICAL AND MICROBIAL PROCESSES

Ippolito Jim*^[1]

^[1]USDA-Agricultural Research Service ~ Northwest Irrigation and Soils Research Laboratory ~ Kimberly, Idaho ~ United States

Most of the recent biochar research has focused on improving the physico-chemical properties of tropical and highly weathered soils, while few studies have investigated effects in arid or semi-arid soils. Results presented will specifically target biochar use in calcareous systems, addressing challenges such as, can biochar: 1) improve the soil fertility status; 2) supply critical plant nutrients; 3) improve soil physical properties; 4) alter microorganism populations and respiration rates; and 5) increase soil C storage? To address these issues, four separate studies (in field, greenhouse, and laboratory) were conducted in calcareous soils. Results were variable and at times dependent on biochar application rate. In general, biochar application caused a short-term decrease in soil NO₃-N content but increased micronutrient (Fe, Mn, Zn, Ni) availability, an important finding in plant-available micronutrient-poor calcareous systems. In some instances, such as when biochar and manure were co-applied, a synergistic effect was observed with respect to nutrient availability. A 2% biochar application improved soil moisture content by 3-7%, and based on regional evapotranspiration rates, could possibly extend crop water availability from 0.4 to 2.5 days; biochar may play an important role under future water-use limits. Increasing biochar application rates increased overall bacterial populations and microbial respiration rates, yet total soil C concentrations were also maintained at greater levels. Overall, our findings suggest that biochar could play a role in improving the environmental quality of calcareous soil systems.

“OVERVIEW OF USDA-ARS BIOCHAR RESEARCH: IMPACTS ON SOIL QUALITY, CONTAMINANT BINDING, AND REDUCTIONS IN GREENHOUSE GASES EMISSIONS”

Novak Jeff^[1]

^[1]USDA-ARS-CPRC ~ Coastal Plains Research Center ~ Florence, SC ~ United States

Biochar is under intensive evaluation by USDA-ARS scientists and cooperators for its many roles, such as an amendment to improve soil fertility, physical conditions, and sequester pollutants. In our evaluations, biochars can be effective sorbents for inorganic and organic compounds, can also sorbed volatile gasses which trigger various plant and microbial responses, and can influence greenhouse gas production/consumption. Biochar's ability to influence these reactions are dependent on pyrolysis conditions, feedstock selection, aging, and the presence of associated volatile components. Understanding how biochar quality is influenced by pyrolytic conditions and feedstock selection led to development of the 'designer biochar principal' where the biochar is engineered to possess chemical and physical features known to improve targeted soil characteristics. Recent laboratory experiments have shown that designer biochars in weathered and aridic soils can selectively improve C sequestration, reduce physical problems, and re-balance soil plant nutrient levels. This presentation will highlight USDA-ARS field and laboratory biochar research projects and will discuss results for the varied uses/applications of biochar.

THE EFFECTIVENESS OF USING BIOCHAR FOR PALM OIL ESTABLISHMENT IN DIFFERENT SOIL TYPES IN COSTA RICA

Benjamin Tamara^{*[1]}, Soto Gabriela^[2], Major Julie^[7], Lerner Robert^[6], Covell Phil^[8], Garro Francisco^[2], Muñoz Marianela^[2], Muñoz Leda^[2], Solorzano Alexander^[2], Joseph Stephen^[5]

^[1]Purdue University ~ Forestry and Natural Resources ~ West Lafayette ~ United States ^[2]CATIE ~ Agroecology ~ Turrialba ~ Costa Rica ^[3]McGill University ~ Soils ~ Montreal ~ Canada ^[4]Forest Trends ~ Agroecology ~ Washington, D.C. ~ United States ^[5]University of New South Wales ~ Electron Microscope Unit ~ Sydney ~ Australia ^[6]Independent Consultant ~ Biochar ~ Oakland ~ United States ^[7]McGill University ~ Faculty of Agricultural and Environmental Sciences ~ Montreal ~ Canada ^[8]Forest Trends ~ Katoomba Incubator ~ Washington, D.C. ~ United States

In the Osa Peninsula in Costa Rica, during 2009 and 2010, four oil palm plantations were established with biochar, from melina (Gmelina melina) timber waste, which was added to the soil. Additional biochar was incorporated into the soil in 2011 at a 1-meter radius around the palms. Five treatments were established in each site (unamended control, urea fertilizer, NPK:10-30-10 fertilizer, biochar + urea, and activated biochar using H₂O₂ or with phosphoric acid+ urea). Additionally in one site we added a partial biochar mineral complex. Growth data, such as height, diameter, number of new leaves, and leaf measurements to determine leaf biomass, have been collected over the past two years. Additionally, production parameters (flower and fruit quantity) were measured for the plants established in 2009. Significant differences were found in the growth parameters for the partial biochar mineral complex in the site that had lower soil fertility (San Juan de Sierpe). The three treatments with biochar additions had higher quantities of flowers and fruit, but only the biochar mineral complex was significantly higher than the NPK, urea, and control treatments. Biochar improves establishment of oil palm plantations and can reduce the time of when fruit production can initiate. Longer term studies on different soils and with more individuals are needed to understand the mechanisms for this improvement.

*Biochar has been proposed as a climate change mitigation option, however, the potential and risks when applied to temperate soils must be evaluated. Biochar is created through the thermal conversion of organic matter through a process known as pyrolysis: the solid char residue is highly recalcitrant, and thus has the potential for long-term carbon storage. Additionally, biochar used as a soil amendment could help reduce the environmental impact of agriculture by localising soil processes within the root zone, thus providing a 'rhizosphere management' approach to managing agricultural soils. To gain understanding of biochar impacts in the rhizosphere, wheat seedlings were grown in rhizoboxes which allowed direct observation of root-biochar interactions, as well as sampling of rhizosphere and bulk soil zones. Our research indicated a localisation effect of nitrogen within the rhizosphere when nitrate was applied to biochar-amended soils (Prendergast-Miller et al 2011). Additional rhizosphere responses are presented following the application of fresh and manipulated chars. Further research is required into biochar-rhizosphere interactions and the potential for localised nutrient management around the root zone. BIOCHAR (IN)STABILITY IN SOILS: THE ROLE OF SOIL ORGANISMS

Ameloot Nele^{*[1]}, Graber Ellen^[2], Verheijen Frank^[3], De Neve Stefaan^[1]

^[1]Ghent University ~ Department of Soil Management ~ Gent ~ Belgium ^[2]The Volcani Center ~ Institute of Soil, Water and Environmental Sciences ~ Bet Dagan ~ Israel ^[3]Centre for Environmental and Marine Studies ~ Department of Environment and Planning ~ Aveiro ~ Portugal

In recent years there has been an increasing number of studies concerning the stability of biochar and its interactions with soil organisms. While it has been suggested that biochar is a nearly inert material in soil, there is a substantial number of studies that reports important C mineralization after the addition of biochars to soils, indicating that soil organisms are stimulated by the addition of biochar as a preferential habitat, or/and that (parts) of the material in biochar may serve as a substrate for soil biota or/and that biochar interacts with soil organic carbon pools. We hypothesize that in order to better understand the mechanisms involved in biochar turnover, we need a thorough mechanistic insight into the interactions between biochar additions and soil biota. Observed biphasic mineralization rates suggest rapid mineralization of labile biochar compounds by microorganisms, with more stable aromatic compounds decomposed at a slower rate. A meta-analysis of data in the literature showed that C-mineralization rates decreased with increasing time, pyrolysis temperature and OC content of the biochars, while a positive correlation was found between the SOC content and C mineralization rates. Soil faunal associations may be altered directly by the addition of biochar or indirectly through the effects of biochar on soil structure and other physicochemical properties and as well as soil microbial communities on which the fauna depend. However, only a few studies on earthworms have been published, whereas other crucial ecosystem engineers such as termites, nematodes, and protozoa have not been reported at all.

The addition of biochar to soil has been shown to have both positive and negative impacts on crop productivity, carbon (C) dynamics and ecosystem services. Many aspects of biochars and their behaviour in soils are not yet fully understood. This includes the crucial question of how stable biochars remain within the soil environment when exposed to soil microorganisms, and what causes observed agronomic benefits of biochar amendment. We hypothesised that biochars contain compounds which are labile and bioavailable to soil microorganisms within their predominantly recalcitrant, condensed polyaromatic structure. We used ¹³C-labeled biochars in conjunction with isotopic analysis of the respired CO₂ and phospholipid fatty acids (PLFAs) to quantify the amount of biochar that was being utilised, and also to identify which groups of microorganisms were responsible for this during the incubation experiment. Nano-scale Secondary Ion Mass Spectrometry (NanoSIMS) was utilised to visually identify C flows within the soil-biochar matrix. We present data that demonstrate the presence of labile compounds in both incubated biochars, their utilisation by soil microorganisms and the effect this has on community structure. Our data also allowed us to estimate the short- and medium-term stability of the added biochars, and to demonstrate and quantify the utilisation and turnover of the bioavailable biochar-C and its partitioning into different groups of microorganisms during their metabolism.

BIOCHAR AS CARRIER FOR PLANT NUTRIENTS AND MICROORGANISMS – A FIRST APPROACH TO ACTIVATION TECHNIQUES

Schmidt Hans-Peter*^[1]

^[1]Delinat Institute for Ecology and Climate Farming ~ Climate Farming ~ Arbaz ~ Switzerland

The soil ameliorating potential of biochar is strongly linked to its impact on nutrient cycling dynamics, sorption capacity and to its ability to change the habitat function for the soil fauna. However, as shown in multiple studies, the addition of pure biochar to agricultural soils will not always have benefits; rather it may even reduce plant growth caused by the (initial) immobilisation of plant nutrients. This capacity may be used to our advantage: The very potent sorption dynamics of biochar could potentially make it an effective carrier for plant nutrients and plant-root symbiotic microorganisms. At the Delinat-Institute, we tried a variety of methods of charging biochars with organic and mineral plant nutrients as well as with potentially beneficial microorganisms. This includes the use of biochar as bulk agent in aerobic composting, in malolactic fermentation and as pre-treatment for liquid manure, but also formulations of mineral carbon-fertilizers. The biochar products were tested in pot trials and also in larger-scale field trials. Results and experiences of these trials as well as different activation methods will be explained. A short overview of the potential of industrial designing of potential biochar-based products will be given.

BIOCHAR AMENDMENT AFFECTS METAL LEACHING FROM MULTI-CONTAMINATED SUBSTRATES: A MICROCOSM STUDY

Fellet Guido^{*[1]}, Contin Marco^[1], Marchiol Luca^[1], Guarino Carmine^[2]

^[1]University of Udine ~ Agriculture and Environmental Sciences ~ Udine ~ Italy ^[2]University of Sannio ~ Biological and Environmental Science ~ Benevento ~ Italy

The application of biochar to soils have been proven to be effective in changing their physical and chemical characteristics (e.g. water holding capacity, nutrient retention, pH and EC). Moreover, its influence on the soil properties extends to the mobility of pollutants. For its intrinsically high resistance to degradation, long term effects are expected. The application of biochar to industrial and mine wastes may be a solution to reduce environmental risks posed by the pollutants release because of leaching into the groundwater. Besides, the reduction in terms of bioavailability of toxic elements and other physical and nutritional modifications to the substrate may be of help to plant growth and therefore to establish a green cover on top of the wastes for a long term stabilization. Wastes from the formerly Pertusola Sud zinc smelter (Crotone, Italy) and the Cave del Predil mining site (Udine, Italy) rich in As, Cd, Pb, Tl and Zn, were mixed with biochars from three different feedstocks at the dose of 3% (DW/DW). Column leach tests were set up to evaluate the effects of the biochars on the mobility of the toxic elements. Soil water was sampled at three depths with Rhyzon® and the leachate at the bottom was collected by gravity. The results on the mobility behavior of the toxic elements as consequence of the type of biochar will be presented. The use of biochar to improve plant growth and reduce metals leaching may be a viable technique.

THE ROLE OF BIOCHAR IN THE PHYTOREMEDIATION OF METAL/METALLOID CONTAMINATED SOILS.

Beesley Luke^[1], Marmiroli Marta^[2], Moreno-Jimenez Eduardo^[3]

^[1]The James Hutton Institute ~ Soils ~ Aberdeen ~ United Kingdom ^[2]University of Parma ~ Environmental Sciences ~ Parma ~ Italy ^[3]Katholieke Universiteit Leuven ~ Environmental Sciences ~ Leuven ~ Belgium

Biochar has been evaluated for its role in improving soil quality and sequestering carbon, with much less attention paid to soil clean-up and remediation. In the following study a hardwood biochar and greenwaste compost alone and in combination were mixed with two contaminated soils (As, Cd, Cu, Pb and Zn) from former industrial sites and, following environmental exposure, pore water was collected and ryegrass (L. perenne L. var. Cadix) germinated to determine the amendments affects on i) solubility/mobility of the elements and ii) uptake and phytotoxicity to ryegrass. Biochar was most efficient at reducing Cd and Zn in pore water, decreasing phytotoxicity to ryegrass, but mobilized small concentrations of As. Copper in pore water was also reduced by a decrease in dissolved organic carbon (DOC) and co-mobility. Greenwaste compost was more efficient for immobilizing Pb than biochar alone but combining greenwaste compost and biochar provided the best conditions for ryegrass growth and yield because of the immobilization of metals and the input of N and P from compost. Despite some reductions in ryegrass shoot concentrations of metals after amendment, the large biomass increase raised harvestable amounts of the metals, increasing food chain transfer potential. An assessment should therefore be made as to whether maximum reductions in plant concentrations or maximum reduction in harvestable amounts of metals are required to ensure amendments may be suitably deployed to maximize their effects.

The feasibility of the currently discussed option of CO₂-sequestration through incorporation of biochars into soils strongly depends on the long-term stability of the biochars and on the lack of negative effects on soil properties. While much is already known about changes in chemical and physical soil properties after biochar incorporation, effects on microbial and enzyme activities have been rarely studied. In this study the stability of maize derived biochar in two soils was examined in a 59 day long incubation with additions of different biochar qualities and amounts. The fresh biochar additions were carried out with a biochar produced by slow pyrolysis of corn silage, one produced by hydrothermal carbonization of corn silage (HTC-biochar) and a commercial mixture of compost and pyrogenic biochar (Palaterra®). Selected treatments received substrate additions of glucose at day 50 of incubation. Respiration was monitored continuously and microbial biomass and enzyme activities were determined at day eight and at the end of the incubation. Through analysis of d13C contents before and after incubation the C-balance is calculated separately for SOM and the added chars. Also, the composition and biological stability of DOC was determined. The results show that the samples with added young HTC-biochar have a higher respiratory loss of carbon dioxide until reaching the basal respiration than the other treatments. Moreover the microbial biomass after the incubation of the samples with HTC-biochar is higher. Enzyme activity patterns are also distinctly affected by the different biochars, but effects generally subside during the course of incubation.

S05.03c -2

EARLY MINERALIZATION OF BIOCHAR: IMPORTANCE OF ABIOTIC AND BIOTIC PROCESSES

Bruun Sander*^[1]

^[1]University of Copenhagen ~ Department of Agriculture and Ecology ~ Frederiksberg C ~ Denmark

The stability of biochar in soil is of importance for the prospect of using biochar application for soil carbon sequestration and for long-term soil improvement. It is well known that a significant fraction of biochar is highly stable in soil but also that CO₂ is released immediately after biochar has been applied to soil. However, not very much is known about the sources and nature of the processes leading to this CO₂ evolution. The purpose of this paper was to investigate the nature of the initial flush of CO₂ evolution. To do this, we made incubations of ¹⁴C labelled biochar produced at different temperatures in soils with different pH and clay contents and in sterilized and non-sterilized soil. To elucidate the role of carbonates, the carbonate content of the biochars was determined. The results showed that carbonate concentrate during or from after biochar production, resulting in significant carbonate contents in the biochar. If carbonate released CO₂ is misinterpreted as mineralization of biochar, mineralization in short-term incubations may be significantly overestimated. In addition to the CO₂ released from carbonates however, there is a small labile fraction of biochar which is mineralized quickly during the first days of incubation by some abiotic process. This is likely to be CO₂ evolved during the oxidation of the surfaces of biochar.

SOIL PRIMING EFFECTS AND THE MINERALISATION OF BIOCHAR FOLLOWING ITS INCORPORATION TO SOILS OF DIFFERENT PH

Luo Yu*^[1], Durenkamp Mark^[2], Lin Qimei^[3], De Nobili Maria^[4]

^[1]China Agriculture University & Rothamsted Research ~ Soil department ~ Beijing ~ China ^[2]Rothamsted Research ~ Sustainable Soils and Grassland Systems Department ~ Harpenden ~ United Kingdom ^[3]China Agriculture university ~ soil department ~ Beijing ~ China ^[4]Udine University ~ soil ~ Udine ~ Italy

We determined the magnitude of the priming effect (PE), i.e. short-term changes in rate (negative or positive) of mineralisation of native soil organic C, following biochar addition, made from *Miscanthus giganteus*, a C4 plant, naturally ¹³C enriched. The biochars were produced at 350 °C (biochar350) and 700 °C (biochar700) and applied \pm ryegrass to a clay-loam soil at pH 3.7 and 7.6. After 87d, biochar350 addition caused PEs equivalent to 250 and 319 μ g CO₂-C g⁻¹ soil, or % positive priming effects of 514 % and 272 %, in the low and high pH soil (based on CO₂-C evolved from the respective control soils), respectively. Biochar700 addition led to much smaller priming effects. The largest PEs occurred at the start of the incubations. By 87d incubation, 0.14 % and 0.18 % of biochar700 and 0.61 % and 0.84 % of biochar350 were mineralized in the low and high pH soil respectively. Ryegrass addition increased biochar mineralisation in all treatments. Our results show that if biochar is used to sequester carbon, PEs may occur, increasing CO₂-C evolved from soil and decreasing soil organic C. A similar conclusion holds for accelerated mineralisation of biochar due to incorporation of fresh labile substrates. We consider that our results are the first to unequivocally demonstrate the initiation and progress of a true PE by biochar on native soil organic C.

Applying biochar to soils is considered to be geoengineering because it has the potential to help mitigate global climate change, although the potential for long-lived changes to fundamental soil properties, processes and functions also warrants the label ‘geoengineering’. Surface albedo is known to be a sensitive parameter in surface-atmosphere energy exchange and in planetary radiative forcing (RF). Considering the potential for changes in soil albedo to influence both global RF as well as local soil processes, through altering soil energy balance dynamics, a detailed knowledge of quantitative relationships between albedo and biochar applications, and resulting topsoil concentrations, for a range of soil types and climates is paramount. Therefore, we developed an experimental dataset of soil surface albedo estimates from spectroscopic measurements on a representative set of soils mixed with increasing amounts of biochar (and soil moisture contents). From this dataset we will estimate the planetary RF under a global biochar application scenario and compare this value to RF values from studies that omitted albedo effects. This work describes a robust first approximation of the effect of changes in soil surface albedo resulting from biochar application and subsequent implications for RF, and discusses important directions for future research.

S05.03c -5

WILL AGED BIOCHARS CONTINUE TO REDUCE N₂O EMISSIONS?

Kammann Claudia^[1], Christoph Finke^[1], Philipp Trulley^[1], Christoph Müller^[1]

^[1]Justus-Liebig-University Gießen ~ Department of Plant Ecology ~ Gießen ~ Germany

It is now well established that many freshly produced biochars (BCs) can significantly reduce N₂O emissions from BC-amended soils. The mechanisms under discussion include NH₃/NH₄⁺ adsorption by the biochar (as documented for acidic BCs), pH or other N-cycling changes, or soil aeration. However, we observed repeatedly that N₂O emissions were even reduced when the increased water-holding capacity had been accounted for. It is unclear to date if the N₂O-emission reducing effect will continue over time, or if, rather, the BC-amended soils will produce larger N₂O emissions in the long run e.g. if the microbial activity and organic carbon besides BC increases. Thus, we investigated (i) compost versus BC-compost (i.e. where BC was co-composted) and (ii) very old BC-soils such as two terra preta, or soil from old German charcoal-making sites, compared to the respective adjacent soils. So far, without further N amendment, no increase in the N₂O emissions from the BC-containing soils and substrates has been observed, although the BC-soils usually had the higher microbial activity and microbial biomass. In the presentation, further N₂O-emission results following NH₄⁺ or NO₃⁻ application to the old-BC soils and substrates will be presented.

BIOCHAR SUPPRESSION OF N₂O EMISSIONS FROM AN AGRICULTURAL SOIL

Case Sean^{*[1]}, Whitaker Jeanette^[1], Mcnamara Niall^[1], Reay David^[2]

^[1]Centre for Ecology and Hydrology ~ Biogeochemistry ~ Lancaster ~ United Kingdom ^[2]University of Edinburgh ~ School of Geosciences ~ Edinburgh ~ United Kingdom

Biochar is biomass that has been partially combusted at a temperature of between 350 and 800°C that is subsequently used as a soil amendment to increase agricultural productivity/efficiency or for carbon sequestration. Previous studies have also shown that adding biochar to soil suppresses soil N₂O emissions under certain conditions. During our experiments, addition of hardwood biochar to soil suppressed N₂O emissions following simulated rainfall events in a low-N (72 % suppression) and high-N agricultural soil (83% suppression). This result was replicated with soil from the same site incubated in-situ with biochar for 10 months (at least a 40 % suppression). We hypothesised that biochar may suppress N₂O emissions by increasing the water holding capacity (WHC) of the soil. Water was added to raise soil to the same WHC (87%) with biochar at a range of amendment rates. Biochar (5% addition) suppressed N₂O emissions by 67%, even when WHC was accounted for. We concluded that the increased WHC of biochar-amended soil cannot explain the suppression of N₂O emissions. Our second hypothesis was that biochar may immobilise inorganic-N in the soil by physical or biological mechanisms, reducing the availability of inorganic-N to N₂O-producing microbes. In this presentation, we discuss our use of stable isotope techniques, adding ¹⁵N-labelled ammonium and nitrate to soil, in order to determine the fate of inorganic-N within biochar-amended soil. We also present results showing the effect of biochar on the abundance of microbial functional groups of soil nitrifiers and denitrifiers.

BIOCHAR CARBON STABILITY AND PRIMING EFFECT IN CONTRASTING SOILS OF AUSTRALIA

Fang Yunying^[1], Singh Balwant^{*[1]}, Singh Bhupinder Pal^[2], Krull Evelyn^[3]

^[1]University of Sydney ~ Faculty of Agriculture, Food and Natural Resources ~ Sydney ~ Australia ^[2]NSW Department of Primary Industries ~ Forestry Research ~ Beecroft ~ Australia ^[3]CSIRO ~ Division of Land and Water ~ Adelaide ~ Australia

There has been growing interest in the application of biochar to soil for agronomic benefits and mitigation of greenhouse gas emissions. However, the stability of biochars in different soil types has not been comprehensively evaluated based on the soil-biochar interactions. Furthermore, there are conflicting observations about the priming effect of biochar on soil carbon (C), which have implications on the net C sequestration potential of biochar in soils. We assessed the stability of two wood biochars (450 and 550°C; Eucalyptus saligna; $\delta^{13}\text{C}$ ~-36‰) and their priming effect on soil organic C mineralisation at three incubation temperatures (20, 40 and 60°C). The biochars (2% w/w) were incubated for one year at 70% WHC with four soils of contrasting mineralogical composition and other properties (Inceptisol, Vertisol, Oxisol, Entisol). The results show that between 0.3 and 7% of added biochar C was mineralised during one year. The lowest mineralization of biochar occurred in the Vertisol amended with 550°C biochar incubated at 20°C, while the highest values was observed in the same soil amended with 450°C biochar incubated at 60°C. Biochar C mineralization rate increased with increasing incubation temperature, and the mineralisation rate of 450°C biochar was consistently higher than the 550°C biochar in all soils. Biochar C stability was also influenced by soil types especially at 40 and 60°C. The biochar application in the Inceptisol caused positive priming of soil-C at all incubation temperatures; whereas in other soils with higher clay content, biochar suppressed the mineralisation of soil-C over time.

LONG-TERM FIELD EXPERIMENTS EXAMINING SOIL AND CROP QUALITY AFTER SEWAGE SLUDGE APPLICATIONS

Mcgrath Steve*^[1]

^[1]Rothamsted Research ~ SSGS ~ Harpenden ~ United Kingdom

Due to environmental and resource use concerns, there is now increased urgency to improve the recycling of N and P. Treated sewage sludges (biosolids) are a useful source of nutrients including N and P, and organic matter. Sewage sludge also contains a number of metals at varying concentrations, depending on the source. Inventories of metal inputs to land in the UK show that although metal concentrations in sludges have decreased, the increase of metal concentration in soils where they are applied is more rapid than with animal manures and certain industrial wastes. Nine field experiments were originally set up to examine the effects of Zn, Cu and Cd on soil microbial activity and long-term soil fertility in 1994-7. This paper highlights results from these experiments from between 1999 and 2005. The concept was to test the additions of metals via sludge up to and slightly beyond the maximum values for soil concentrations of Zn, Cu and Cd (300, 140 and 3 mg/kg respectively) given in the EU Sludge Directive (86/278/EEC). No consistent effects were found on crop yields (herbage and wheat), but some were detected on the abundance of microbes in soils. However, Zn and Cu are biologically essential micronutrients. For example, there is a need to improve the Zn status of staple cereal grains for human health reasons. Sewage sludge can increase Zn concentrations in wheat grain for at least 2-8 years after application to soil. Positive effects are needed, and adverse effects are to be avoided.

CRUCIAL: A LONG-TERM FIELD TRIAL TO ASSESS WASTE RECYCLING IMPACTS ON ENVIRONMENT AND PRODUCTIONS SYSTEM INTEGRITY

Magid Jakob^[1], Poulsen Pernille Hasse Busk^[1], Lekkfeldt Jonas Duus Stevens^[1], Brandt Kristian Kofoed^[1], Nybroe Ole^[1], Holm Peter^[2], Kjaergaard Charlotte^[3], Jensen Lars Stoumann^[1]

^[1]Copenhagen University ~ Agriculture and Ecology ~ Copenhagen ~ Denmark ^[2]Copenhagen University ~ Basic Sciences and the Environment ~ Copenhagen ~ Denmark ^[3]Aarhus University ~ Department of Agroecology ~ Tjele ~ Denmark

We established the 'CRUCIAL' long-term field trial in 2003, in order to meet the societal demands for assuring that recycling of waste can be done without compromising environmental quality and production system integrity. The facility was established based on the rationale that by approaching the known limits for a number of heavy metals below which no profound disturbance should be observed on key soil ecological functions, it should be possible to discern if some of the many unknown components in the composite urban waste as well as agriculturally based fertilizers have measurable impacts. The following treatments were established: human urine, sewage sludge, degassed and subsequently composted organic municipal waste, deep litter, cattle slurry, cattle manure, NPK fertilizer, unfertilized but with clover undersown and an unfertilized control. Presently we have a factor 2 difference in soil organic matter level between the accelerated rate of municipal waste compost amendment and the unfertilized control. Similarly we have large differences in soil fertility and crop yield. Results obtained from a mid-term baseline soil biological characterization indicate no negative effects on soil biological function by use of urban waste products, and high throughput pyrosequencing of bacterial DNA indicates only very minor changes of microbial diversity across treatments. Antibiotic multiresistant pseudomonads increased after treatment with both animal and urban waste, but after 9 weeks the numbers were no different from the control treatment. Ongoing work on leaching of metals and bacteria will be briefly described, and potentials for future collaboration highlighted.

FATE OF TRACE ELEMENTS IN ARABLE CROP SYSTEMS AMENDED WITH URBAN COMPOSTS DURING 10 YEARS

Michaud Aurélia^[1], Cambier Philippe^[1], Mercier Vincent^[1], Bodineau Guillaume^[2], Doublet Jérémy^[3], Houot Sabine^[1]

^[1]INRA ~ UMR INRA - AGROPARISTECH EGC ~ Thiverval - Grignon ~ France ^[2]INRA ~ GBFOR ~ Orléans ~ France

^[3]VEOLIA Environnement ~ Recherche et Innovation ~ Limay ~ France

A field experiment upon long-term effects of using different organic waste products (OWP), including three urban originated composts, has been monitored during more than 10 years. It concerns arable crop systems representative of the central Paris Basin, and involves OWP and techniques close to French regulations and farmer practices. The synthesis of all results upon trace element contents and fluxes aimed to answer the following questions: what are the chemical impacts on the surface soil layer and the crop quality (wheat, maize, barley)? Does the balance between OWP and atmospheric inputs and the crop and leaching outputs match the stock variation of trace elements in the plough layer? The Cu and Zn stocks of all amended plough layers increased after several applications, in close relationship with the cumulated metal balance. The variations concerning Cr, Ni and Pb were not significant, due to relatively low inputs, and for Pb to data dispersion. Cd and Hg did not significantly vary in amended plots, but Cd progressively appeared lower in the control compared to all OWP treatments; and Hg after 10 years became significantly lower in the control compared to two treatments (municipal solid waste and sewage sludge composts). Indeed, Cd and Hg stocks decreased in the control plough layers between 1998 and 2009. The study also pointed out a progressive decrease of most analysed trace metals in most used OWP. The contents of the 7 trace metals in grains and crop residues were overall not changed by OWP applications.

FATE OF HUMAN ENTERIC VIRUSES SUPPLIED WITH WASTEWATER IRRIGATION: A REVIEW

Renault Pierre*^[1], Bon Fabienne^[2]

^[1]INRA ~ EMMAH ~ Avignon ~ France ^[2]Université de Bourgogne ~ LIMA ~ Dijon ~ France

Wastewater reuse in irrigation may partly meet the increasing water requirement that results from climate change, population growth and diversification of water uses. However, wastewaters may contain human enteric viruses, and their transmission through foods and drinks after environmental transport has become an emerging topic with the development of new molecular detection methods. Norovirus, hepatitis A viruses, Enterovirus (especially Coxsackievirus and Echovirus) and Rotavirus are sometimes considered in the prioritizing pathogens for future regulations in drinking water. They have been detected at the entrance and exit of wastewater treatment plants, in soils and in aquifers. Enteric viruses may be rejected in the environment at high concentrations, whereas infectious levels are very low. They are extremely resistant. During irrigation, they may be dispersed as aerosols or move at the surface or within the soil, and either reach the aquifer or be internalized in some crops after root absorption. In soils, virus behaviour varies with species, strain and virus conformation. Their transport, immobilisation on solids and inactivation are coupled with each other: virus may move sorbed or not on colloids, and their inactivation may be accelerated or slowed down by their adsorption on minerals. Virus immobilization depends on the virus, the solid phases, and the physical-chemical characteristics of the soil solution (pH, ionic strength, mineral cations and anions, organic compounds). Immobilization is controlled by various forces (electrical, van der Waals, hydrophilic/hydrophobic ...) and sometimes may explain virus inactivation due the mechanical effect of the adsorption on the stability of the viral capsid.

CHALLENGING AREAS FOR LIFE CYCLE ASSESSMENTS OF WASTE APPLICATION TO AGRICULTURAL LAND

Bruun Sander*^[1], Birkved Morten^[2], Magid Jakob^[1], Ten Hoeve Marieke^[1], Stoumann Jensen Lars^[1], Hauschild Michael^[2]

^[1]University of Copenhagen ~ Department of Agriculture and Ecology ~ Frederiksberg C ~ Denmark ^[2]Technical University of Denmark ~ Department of Management Engineering ~ Lyngby ~ Denmark

The purpose of this presentation is to review the LCA approaches that have been used to quantify the potential impacts of waste application to arable land with special focus on challenging areas to LCA modelling. Recycling nutrients to agriculture most frequently requires waste application to arable land. A range of environmental impacts is associated with this type of nutrient recycling, including eutrophication, odour, global warming, acidification and toxicity. One of the broader methodological approaches which has been applied to assess the potential environmental impacts related with nutrient recycling via arable land is life cycle assessment. The identified challenging areas for LCA modelling of application of waste to agricultural land are: 1) Odour emissions, which consists of compounds that are rarely measured and for which no generally accepted impact assessment method currently exists 2) Carbon sequestration associated with organic wastes for which the time boundary is arbitrarily defined 3) Assessing the relative fertilizer value and environmental impact of P added with the waste, which strongly depends on the chemical form in which it exists 4) Definition of spatial boundaries and estimation of emissions of heavy metals and organic pollutants from arable land used for waste application.

CARBON CAPTURE BY CALCITE PRECIPITATION ON 'WASTES' IN URBAN SOILS

Manning David*^[1], Washbourne Carla-Leanne^[1], Renforth Phil^[2]

^[1]Newcastle University ~ Civil Engineering & Geosciences ~ Newcastle upon Tyne ~ United Kingdom ^[2]Oxford University ~ Earth Sciences ~ Oxford ~ United Kingdom

Urban soils commonly contain wastes derived from demolition of pre-existing buildings, and also clinker and other artificial materials. We have shown that urban soils from a number of locations contain pedogenic calcite (CaCO_3), with carbon contents over 3 m soil depth typically averaging 300 T C/ha (Renforth et al., Applied Geochemistry 2009). Carbon isotope studies show that 50% or more of the carbon in the calcite is derived from the atmosphere, primarily through high-pH driven hydroxylation of CO_2 within the soil solution, which is promoted by biologically mediated rapid dissolution of the waste material in the soil. This leads to a conceptual model in which plant growth provides a source of CO_2 within the root zone as a consequence of root respiration and microbial degradation of plant root acid exudates. Corrosion of artificial calcium silicate minerals by plant root exudates releases Ca, which combines with carbonate in solution to produce calcite. The amounts of waste arising from demolition activity are substantial. Typically, demolition involves the use of crushers on site so that secondary aggregates can be recovered and sold. This process inherently produces a fine fraction, and that is often retained on site, forming part of the subsoil. We estimate that sufficient demolition waste is produced globally to provide a carbon capture potential of 24-100 MtC/year if incorporated into soils as part of an urban development (Renforth et al., Environmental Science & Technology 2011). This is a consequence of natural soil-forming processes, adding value to other ecosystem services.

COMPLETE MATERIAL CYCLES BY MATERIAL FLOW MANAGEMENT USING THE TERRA-PRETA-TECHNOLOGY IN THE BOTANIC GARDEN BERLIN IN TERMS OF RESOURCE EFFICIENCY AND CLIMATE PROTECTION (TERRABOGA)

Wagner Robert^[1], Terytze Konstantin^[1], Schatten Rene^[1], König Nadine^[1], Vogel Ines^[1], Friede Karin^[1], Worzyk Florian^[1]

^[1]Freie Universität Berlin ~ Earth Sciences, Geoecology ~ Berlin ~ Germany

The main focus of this project is the efficient utilization of biogenic waste and residual materials like green waste and faeces of employees and visitors. The research and development project intends to complete the internal, small scale material cycles in the Botanic Garden Berlin. The aim is to make a contribution to sustainable soil management within Urban Farming in terms of carbon reduction and the impacts of climate change processes. The Berlin Botanic Garden produces around 1500 m³ of green waste, pruning waste, grass cuttings and wood. Much of this is still unused and is disposed of in a way that is both energy and cost intensive, as well as the sewage from employees and the annual 260.000 visitors of the Botanic Garden Berlin. In contrast, around 350 m³ of compost and fertilizer has had to be bought in each year. The total biomass is planned to be turned into nutrient-rich black earth substrates (premium potting soil) by using the "Terra Preta-Technology". Due to its high stability and functionality biochar provides long-term storage for nutrients and water for plants as well as the possibility for long-term carbon storage. The environmental relief potential of the closed material cycle and the plant growth effectiveness of biochar substrates will be determined by means of tests in laboratories and field studies taking into account chemical and physical as well as biological parameters. Currently diverse chemical, physical and biological examinations are performed. First results will be presented.

EMERGENT POLLUTANT REMOVAL FROM SOIL AMENDMENTS

Akmehmet Balcioglu Isil^[1], Bilgin Öncü Nalan^[1], Ötker Uslu Merih^[2], Cengiz Murat^[3]

^[1]BOGAZICI UNIVERSITY ~ INSTITUTE OF ENVIRONMENTAL SCIENCES ~ Istanbul ~ Turkey ^[2]University of Windsor ~ Civil and Environmental Engineering ~ Ontario ~ Canada ^[3]Uludag University ~ Department of Pharmacology and Toxicology, Faculty of Veterinary Medicine ~ Bursa ~ Turkey

Soil amendments, sewage sludge and manure, are important sources of soil contamination with emergent pollutants as they may contain considerable amount of antibiotics. Appropriate treatment technologies are required to overcome antibiotic pollution in soil amendments for the prevention of the transfer of antibiotics and antibiotic resistant bacteria to soil. In the present study sewage sludge and manure that were synthetically contaminated with antibiotics (tetracyclines, sulfonamides and quinolones) were subjected to an integrated treatment process consisting of extraction pretreatment and chemical oxidation at various experimental conditions. Additionally, the destruction of antibiotic-resistant microorganisms in manure was investigated. In separate experiments, the removal the *tetM* gene and its host, *Escherichia coli* HB101 by chemical oxidation processes was examined. Although ozonation, Fenton oxidation, and persulphate treatment processes provided high removal performance for antibiotics from the manure only thermally activated persulfate treatment was able to complete destruction of antibiotics. On the other hand, for the sludge up to 98% of antibiotic removal was achieved by integrated ozonation process. This process also provided significant metal solubilization and it increased the fertilizer value of the sludge due to probable complexation of magnesium with the nutrients, which was indicated by the decrease in the phosphate and ammonia concentrations. Despite the high organic content of manure, 99% bacterial inactivation was obtained by the ozonation process and the band intensity of the *tetM* gene gradually decreased by increasing the dose of oxidant. However, significantly high doses of oxidants would be required to completely eliminate bacterial pollution in manure.

PREDICTING CONSTRUCTED URBAN SOIL SUSTAINABILITY: IMPACT OF WASTE ORGANIC MATTER ON SOIL PHYSICAL PROPERTIES

Cannavo Patrice*^[1], Vidal-Beaudet Laure^[1], Grosbellet Claire^[2], Forget-Caubel Virginie^[1]

^[1]UPSP Ephor ~ AGROCAMPUS OUEST Centre d'Angers ~ Angers ~ France ^[2]Union Nationale des Entreprises du Paysage ~ UNEP ~ Paris ~ France

Exogenous organic matter has a positive impact on agricultural soil physical properties. In some urban situations, the wide availability of waste organic matter and the necessity of restructured the soils, lead to the addition of large quantities of organic matter. Our objectives were to measure in soil reconstituted with high levels of OM: (1) the effects of OM decomposition on the evolution of physical properties, (2) to evaluate the sustainability of the soil system by modelling some soil physical properties at a long-term period (i.e 20 years). We monitored throughout a 5-yr experimental study, physical properties of urban soils placed in 600 L containers. The top layer was a sandy loam amended with 40% by volume of organic compost – a sewage sludge and wood chip compost or a green waste compost – laying on a layer of sandy loam. Organic matter had significant effects on the soil physical properties compared to the control with a significant decrease of the soil bulk density and a significant increase of the structural stability. Organic matter modified the aggregate organisation and the pore distribution which contributed to a better infiltration rate. These good properties induced by organic matter were still maintained 5-yr after placement. Using our results and correlation equations between organic matter and soil physical properties, it was possible to determine by extrapolation soil physical properties 20 years after placement. Then, we used HYDRUS model to estimate soil water fluxes. We observed that urban soil sustainability depended on the waste organic matter nature.

Reduced tillage practices have received considerable attention due to many projected benefits. However the literature hosts many arguments of contradiction on soil physical properties and gas fluxes on adoption of reduced tillage. The objective of this study was to assess the effect of conventional and no-till practices on pore dynamics and release of CO₂ in soils of contrasting textures (clay and sand) and different traffic regimes. Intact soil cores were subjected to X-ray Computed Tomographic scanning and analysed to reveal their undisturbed 3-D pore structure. The different tillage, traffic and soil textures created contrasting soil structures with a strong variation in porosity. A significant positive linear relationship was found between mean CO₂ flux and total soil porosity ($R^2 = 0.62$, $P < 0.001$) and between surface area of pores ($R^2 = 0.3247$, $P < 0.05$). The multiple regression analysis of CO₂ emission with soil organic carbon, loss on ignition, microbial biomass carbon, soil organic carbon stock and porosity showed the significant effect of porosity on CO₂ emission over other parameters. The fitting of soil microbial biomass carbon, loss on ignition, bulk density, soil organic carbon did not explain additional variation in the CO₂ fluxes over and above porosity. This data highlights that management practices that impacts on soil porosity may have large impacts on soil C dynamics. However, the net impact of porosity on soil C storage and net green house gas fluxes in relation to different tillage practices and soils types is yet not understood and needs further investigation.

S06.01a -2

EFFECTS OF AGRICULTURAL TILLAGE PRACTISE ON GREEN HOUSE GAS BALANCE AND DYNAMICS OF AN ARABLE SOIL IN A LONG TERM FIELD EXPERIMENT

Munch Jean Charles^[1], Rolf Schilling^[1], Bernard Ruth^[1], Roland Fuss^[2]

^[1]Helmholtzzentrum Muenchen ~ Soil Ecology ~ Neuherberg ~ Germany ^[2]Johann Heinrich von Thünen Institute ~ Institute of Agricultural Climate Research ~ Braunschweig ~ Germany

Although it is desirable to minimize esp. N₂O emissions while maintaining high crop yields it is still poorly understood how green house gas emissions may be steered by agricultural management practise, i.e. tillage and fertilization systems. In an ongoing long term field experiment at the research farm Scheyern, Bavaria, an arable field with one homogenous soil formation was transformed into plots in a randomized design 16 years ago. Since then, they are managed using conventional tillage (CT) and no tillage (NT) as well as low and high fertilization. A conventional crop rotation is maintained on the field. Starting 2007, CO₂ and N₂O emissions were monitored continuously for 3 years. Furthermore water content, temperature and redox potential were measured in-situ as they are major factors on microbial activity and denitrification. Soil was sampled from the Ap horizons of the plots about twice a month and extracts from these soil samples were analyzed for dissolved organic carbon (DOC), ammonium, nitrate/nitrite, and dissolved organic nitrogen (DON). According to the results soil density and hydrology are clearly affected by tillage practise. DOC is more affected by tillage while concentration of nitrogen species is controlled mainly by fertilization. There are distinct differences in redox potential between CT and NT plots with CT plots having more anaerobic periods. CO₂ and N₂O emissions exhibit a clear seasonal pattern and are affected by both tillage system and fertilization.

S06.01a -3

GREENHOUSE GAS MITIGATION OPTIONS FOR CALIFORNIA AGRICULTURE

Six Johan*^[1]

^[1]University of California - Davis ~ Department of Plant Sciences ~ Davis ~ United States

In California, agriculture is responsible for 8% of the total GHG emissions, with 12.5% emitted as CO₂, 37.5% as CH₄, and 50% as N₂O. Over the past several years, however, growers and researchers have teamed up to develop economically feasible practices to mitigate GHG emissions within California agriculture. One of the main challenges before effective mitigation practices can be developed, is obtaining accurate estimates of current GHG emissions due to the high temporal and spatial variation, especially of N₂O, across crop types, soil types, and climates. We measured background N₂O emissions from perennial cropping systems (vineyards and almond orchards); compared conventional versus integrated management in tomato crops; and tested the effect of biochar amendments on N₂O emissions within vegetable crops and walnut orchards. Vineyard N₂O emissions without and with a leguminous cover crop ranged from 0.2 to 2.0 kg N₂O-N ha⁻¹ yr⁻¹, respectively, while the almond orchard averaged 0.4 kg N₂O-N ha⁻¹ yr⁻¹. The conventional tomato cropping system yielded 2.1 kg N₂O-N ha⁻¹ yr⁻¹ while the integrated system less than half that, with only 0.9 kg N₂O-N ha⁻¹ yr⁻¹. Results from a walnut biochar study show slight increases in N₂O emissions compared to the untreated control, however, reduced emissions were found when the same biochar was applied to lettuce crops. These results indicate the need for further research in this area, coupled with more accurate field measurements in order to foster adoption of these practices among farmers as well as policy makers.

S06.01a -4

ORGANIC AGRICULTURE – GHG SAVINGS THROUGH SOIL CARBON SEQUESTRATION?

Leifeld Jens*^[1], Jürg Fuhrer^[2]

^[1]Agroscope Research Station ART ~ Air Pollution / Climate Group ~ Zurich ~ Switzerland ^[2]Agroscope Research Station ART ~ Air Pollution / Climate Group ~ Zurich ~ Switzerland

Agriculture directly contributes around ten percent to the global anthropogenic greenhouse gas emissions with an even higher share when CO₂ from land converted for agriculture is included. Amongst options to reduce agriculture-related emissions management-induced change in soil organic matter (SOM) content, termed soil carbon sequestration, is thought to provide significant relief as it may offset most of the agricultural CH₄ and N₂O emissions. Organic farming is considered particularly beneficial because of supposedly high sequestration rates and reduced N₂O emissions. Agricultural management controls SOM content in two ways, residue input and rate and efficiency of SOM turnover. Organic farming yields are often much below that of conventional farming making less plant residue available for soil carbon built-up. Only under non-sustainably high inputs of external organic matter (e.g. additional manure) organic farms sequester more or loose less soil carbon than conventional ones, making it very unlikely that higher inputs are a powerful driver for the hypothesized potential in organic agriculture. The second control, changes in rates and efficiencies of SOM turnover requires that microorganisms in organically managed soils have lower specific activities or use their substrate more efficiently. Data from field experiments and farm comparisons suggest no systematic difference in rates or efficiencies between conventional and organic farming. Under very limiting nutrient conditions soils may even loose organic matter. Based on these results the claim for GHG savings through organic farming is, at least at the sequestration side, premature at best and longer-term impairment of soil fertility cannot be excluded.

S06.01a -5

SIMULATING SOIL ORGANIC CARBON STOCK CHANGE IN JAPANESE AGRICULTURAL LAND WITH THE ROTHC MODEL

Shirato Yasuhito^{*[1]}, Yagasaki Yasumi^[1]

^[1]National Institute for Agro-Environmental Sciences ~ Natural Resources Inventory Center ~ Tsukuba ~ Japan

We calculated the carbon sequestration potential of Japanese agricultural soils. At first step, the Rothamsted carbon model (RothC) was tested using long-term experimental data sets in Japan. The model needed to be modified for Andosols and for paddy soils concerning unique mechanisms of soil carbon (C) dynamics of these soils while the model adequately simulated changes in the soil C content with time in non-volcanic ash upland soils. After the validation and modification of the model at plot scale, we estimated the C sequestration potential by organic matter application at country scale by applying the model at 100 m resolution from 1970 to 2020. We constructed a simulation system which linked the RothC model with spatial data such as weather, soils, land use, and activity data (the amount of C input to soils by crop residue or manure) including two different scenarios in future; 1) BAU: business as usual and 2) C sequestration scenario which increase C input to soils. The results of simulation showed that SOC in Japanese agricultural lands tended to decrease over time in most combination of soil types and land use. In addition, area of agricultural land decreased largely during 1970-2020. As a result, accounting of the amount of changes in SOC by the net-net accounting method following Kyoto protocol resulted in net sink of CO₂ because the rate of SOC decline was greater in 1990 (base year) than recent years (assumed commitment period).

USING SOIL ORGANIC MATTER TO INITIALIZE THE ROTHC CARBON TURNOVER MODEL: A PEDOTRANSFER FUNCTION

Weiermueller Lutz^[1], Graf Alexander^[1], Herbst Michael^[1], Vereecken Harry^[1]

^[1]Forschungszentrum Juelich GmbH ~ IBG-3 Agrosphere Institute ~ Juelich ~ Germany

Modelling of carbon turnover is an appropriate tool to estimate changes in soil carbon stocks as a response to modifications in land use or climate change. In general, carbon turnover models are nowadays used not even at the point scale but also on regional and continental scales. Hereby, the Rothamstadt Carbon Model (RothC) seems to be well suited due to its simplicity and easy implementation. For the initialization of the RothC model knowledge about the carbon pool sizes is essential which can be drawn either from physical fractionation or equilibrium model runs, but both approaches are time consuming and tedious. In the study presented two different pedotransfer functions (PTF) were developed to estimate the resistant plant material (RPM) pool based either on fractionated or simulated RPM data. As an independent variable only Corg data are necessary, which are easily available at most scales. The results showed that there is a linear relation between Corg and RPM. To estimate the associated error induced by the use of the PTF simulation runs were performed for a 100 year time period and crop rotation as well as manure application and different clay contents. The results indicate that the maximum relative errors are small (< 10 %) and decline to be less than 5 % after 100 years. Additionally, absolute errors are in the range of the measurement error for soil organic carbon measurements. Therefore, we propose to use the PTF directly to initialize the RothC model.

Also under future environmental conditions, agricultural nitrogen use is expected to remain the leading cause of reactive nitrogen (Nr) release to the environment. Here we summarize potential mechanisms which may affect denitrification and associated nitrous oxide (N₂O) emissions in/ from agricultural systems under future environmental conditions. Though changes in climate, specifically in temperature and precipitation, are likely to directly affect denitrification rates and N₂O emissions, we identified several indirect mechanisms of global change which may potentially override direct effects. Among these are a) landscape scale changes of hotspots of denitrification: while the importance of upland soils for denitrification may decrease due to limitations in soil moisture the importance of riparian areas as denitrification hotspots may further increase due to the increased likeliness of flooding events leading to more frequent occurrences of aerobic-anaerobic cycles in riparian areas and, thus, increased denitrification, b) increased provision of labile carbon substrates via plant root exudation in the rhizosphere under elevated atmospheric carbon dioxide concentrations, leading to increased microbial activity and higher denitrification rates in agricultural subsoils, thereby potentially reducing rates of nitrate leaching from agricultural soils and c) increased ammonia (NH₃) volatilization from agricultural systems leading to increased denitrification rates and N₂O emissions downwind from ammonia emission sources. Obviously, under future environmental conditions the mentioned mechanisms would further strengthen the regional disjunction of areas of Nr application from those of Nr removal by denitrification, thereby calling for a reappraisal of the importance of indirect emissions of N₂O from agricultural Nr use.

Conversion of grassland to arable land often causes enhanced greenhouse gas emissions (CO₂, N₂O, CH₄) to the atmosphere. However, prediction of such effects is uncertain so far because emissions may differ depending on site and soil conditions. We aim to evaluate the impact of grassland-to-arable-conversion on N₂O fluxes, CO₂ source processes as well as to total microbial and fungal biomass. A four times replicated randomized plot experiment with (i) mechanical conversion (ploughing, maize), (ii) chemical conversion (broadband herbicide, maize per direct seed) and (iii) continuous grassland as reference was started in April 2010. Gas fluxes were measured weekly, soil microbial biomass three times a year. The development of N₂O emissions is affected by soil moisture and application of fertilizers, as well as cultivation dates. Microbial biomass before conversion shows a typical spatial distribution with decreasing biomass with increasing soil depth. Chemical conversion did not affect the depth distribution of the microbial biomass, but slightly decreased its overall amount in all soil depths. Mechanical conversion caused a shift in the depth distribution of the microbial biomass (highest amount in 15 – 20 cm). Annual N₂O emissions were three to four times higher within the first year after both, chemical and mechanical conversion in comparison to continuous grassland. We will report ¹³C/¹²C ratios of CO₂ fluxes to elucidate the contribution of different organic C-pools to the total CO₂ flux.

Atmospheric CO₂ concentrations are rising with accelerating speed, soon crossing the 400 ppm concentration benchmark. Although CO₂ is a primary plant nutrient, the beneficial effects of this "CO₂ fertilization" on plant growth are often reduced or absent factors such as drought or nutrient deficiency limiting. It is well known that warming accelerates decomposition of soil C, i.e. poses a positive feedback loop danger to the earths' climate system. However, much less is known on the dangers of rising CO₂ concentrations on positive feedback dangers. We investigated continuously over 12 years now the ecosystem respiration, N₂O emission and CH₄ fluxes in an continuously running free-air CO₂ enrichment study in temperate grassland near Gießen, Germany. The ecosystem lost any additionally fixed CO₂ under elevated CO₂ quickly back to the atmosphere via ecosystem respiration which was predominantly stimulated during autumn-winter. The N₂O emissions more than doubled under elevated CO₂ over the entire FACE time, while methanotrophic CH₄ uptake was reduced. At the same time, the soil-C content or aggregation did not increase; rather, the entire site lost soil organic carbon over the years which was not prevented by the CO₂ enrichment. In balance, almost all of the roughly +10% increase in plant yield must be charred into stable biochar and added to the soil, to compensate for the CO₂-equivalents that were released under elevated CO₂ due to stimulated N₂O emissions. Thus, rising atmospheric CO₂ might have a "take two for the price of one" effect on other soil-GHG releasing processes.

TOWARDS A UNIFIED FRAMEWORK FOR MEASURING AND MONITORING SOIL ORGANIC C STOCKS IN AGRICULTURAL SOILS

Beare Mike^{*[1]}, Angers Denis^[2]

^[1]New Zealand Institute for Plant & Food Research ~ Soil, Water & Environment Group ~ Christchurch ~ New Zealand

^[2]Agriculture & Agri-Food Canada ~ Soil Science ~ Quebec City ~ Canada

The development of robust protocols for soil carbon (C) measurement are important to quantifying soil C stocks and rates of change over time. These measurements are essential to developing and verifying national greenhouse gas emission inventories and emission trading schemes as well as identifying management practices that mitigate soil C losses or enhance soil C sequestration. Procedures for measuring C concentrations in soil samples are well established, though some notes of caution are warranted when comparing results obtained with different technologies. In contrast, there are few widely agreed protocols for sampling and calculating soil C stocks and these remain a potentially significant source of error. Accurate estimates of soil C stocks require the collection of samples that adequately represent the land units of interest (e.g. field, slope position, experimental plot) to a depth that reflects any potential changes imposed by management or environmental (e.g. climate, erosion) factors. The size, number and depth of samples taken depend on the vertical stratification and heterogeneity of soil C across the land unit. Factors such as tillage depth, rooting depth, row width, crop residue placement, bed height and wheel tracks are important considerations. Accounting for known differences in soil mineralogy, texture, drainage and slope position is also important. We will present several case studies to outline the key assumptions and critical differences between different sampling and calculation procedures and propose steps toward a unified framework for measuring soil C stocks.

SEASONAL METHANE DYNAMICS IN THREE TEMPERATE GRASSLANDS ON PEAT

Schäfer Carolyn-Monika*^[1], Elsgaard Lars^[1], Conrad Ralf^[3], Petersen Søren O.^[1]

^[1]University of Aarhus ~ Department of Agroecology ~ Tjele ~ Denmark ^[2]Max Planck Institute for Terrestrial Microbiology ~ Department of Biogeochemistry ~ Marburg ~ Germany ^[3]Max Planck Institute for Terrestrial Microbiology ~ Department of Biogeochemistry ~ Marburg ~ Germany

*Drained peatlands are considered to be insignificant CH₄ sources, but the effect of drainage on CH₄ cycling has not been extensively studied. We investigated seasonal dynamics of CH₄ in two fen peat soils and one bog peat soil under permanent grassland in Denmark. Soil CH₄ concentrations were measured several times throughout the year in parallel to a one year CH₄ flux monitoring campaign with static chambers. In addition, archaeal communities at different depths were assessed via molecular fingerprint (T-RFLP) analysis. Methane fluxes were negligible even though soil CH₄ concentrations of up to 155 and 1000 $\mu\text{mol CH}_4 \text{ dm}^{-3}$ were measured in one of the fen peats and in the bog peat, respectively. Significant CH₄ concentrations were observed above the water table and methanogens were detected throughout the soil profile at these two sites. Methane production potentials determined in a laboratory incubation assay confirmed the presence of viable methanogens in the upper parts of the bog peat soil. Methane was liberated from the peat at rates of up to 3.3 mg CH₄ m⁻² h⁻¹ via the aerenchymous plant *Juncus effusus* L. No methanogens were detected in the second fen peat which, in contrast to the other two sites, had high sulfate concentrations. Peat type and the distribution of aerenchymous plants should be considered before dismissing temperate grasslands on peat as CH₄ sources. Also, data on the distribution of methanogens should be further pursued to allow interpretations regarding their influence on soil CH₄ concentrations in comparison to environmental factors.*

ARE SHIFTS IN SPATIAL NICHE OF METHANOTROPHS REGULATING SOIL METHANE UPTAKE?

Niklaus Pascal^[1], Stiehl-Braun Petra^[2], Rime Thomas^[1], Ellen Kandeler^[3], Hartmann Adrian^[2]

^[1]University of Zürich ~ Institute of Evolutionary Biology and Environmental Studies ~ Zürich ~ Switzerland ^[2]ETH Zürich ~ AGRL ~ Zürich ~ Switzerland ^[3]University of Hohenheim ~ Soil Science ~ Hohenheim ~ Germany

The oxidation of methane by soil methanotrophic bacteria is the only globally relevant biological sink for atmospheric methane (CH₄). The activity of these bacteria is affected by many factors, both natural and anthropogenic. Of particular importance are effects of nitrogen fertilizers, which often reduce the sink activity of the respective soils. Interestingly, N-fertilizer effects are only found in some soils, whereas the soil methane sink is not inhibited in others. We have studied N fertilizer effects in several natural and agricultural soils, testing the hypothesis that spatial shifts in the niche of soil methanotrophs under N fertilization and climate change are a mechanism modulating the soil-atmosphere exchange of methane. The spatial distribution of CH₄ assimilation and its response to fertilizer application and climate change were studied in several field experiments in grassland, using a novel isotopic technique allowing the mapping of methanotrophic activity at a resolution of approximately 100 micrometers. Here, we present a synthesis of results from these studies. Our data indicates that even relatively pronounced effects on methanotrophic activity in the top soil can be alleviated by increased methane oxidation in deeper soil layers (i.e. by a shift in activity down the soil profile). Overall, our results demonstrate that an understanding of the spatial dimension of the interactions between the involved processes needs to be developed in order to infer the ecosystem-level methane sink under disturbance.

SENSITIVITY OF SOIL RESPIRATION WITH RESPECT TO MULTIPLE ENVIRONMENTAL FACTORS

Sierra Carlos*^[1]

^[1]Max Planck Institute for Biogeochemistry ~ Biogeochemical Process ~ Jena ~ Germany

The sensitivity of soil respiration to global environmental change is a topic of prominent relevance for the global carbon cycle. Much attention has been given to the temperature sensitivity of soil respiration, a topic still controversial in which consensus has been elusive. Respiration however, depends on multiple factors that are being altered simultaneously as a result of global environmental change. For this reason it is important to study the overall sensitivity of respiration with respect to multiple and interacting drivers. I present here a theoretical framework for the development of experimental and modeling studies that allows a comprehensive understanding of the response of respiration in the context of global change. This framework is based on simple concepts from multivariate vector analysis. To demonstrate its usefulness I present some examples on how these basic concepts can be applied to resolve some controversies in the 'temperature-quality' debate. In addition, I present some hypotheses about the absolute sensitivity of respiration with respect to simultaneous changes in temperature and moisture. At the global level, tropical peatlands appear to be more sensitive than any other ecosystem including boreal and arctic peats.

S06.01c -2

SOIL ORGANIC CARBON SEQUESTRATION IN GRAZING SYSTEMS OF THE SOUTHEASTERN USA

Franzluebbers Alan*^[1]

^[1]USDA ~ Agricultural Research Service ~ Watkinsville Georgia ~ United States

Improved pasture management systems are needed to restore soil quality, sequester soil organic C, and build the productive capacity of soils in grassland environments so that (1) precipitation can be effectively utilized by plants, (2) water runoff and contaminant transport can be minimized, (3) natural nutrient cycling processes can be restored to rejuvenate long-term fertility, and (4) productive capacity of soils can be fully realized to produce the food, feed, fiber, and fuel needs of the future. Grazing lands in the eastern USA are managed primarily for introduced plant species that have high forage production potential or that fit a niche with a farming system. Moderate grazing of pastures may be the most effective strategy for storing soil organic C, because return of dung to the soil surface has positive effects on soil surface properties, including soil microbial biomass and mineralizable C and N. Grazing land managed with moderate grazing pressure, i.e., utilizing forage to an optimum level without compromising regrowth potential, can (1) provide economic opportunities with low risk for landowners, (2) improve degraded land by building soil fertility, (3) improve water utilization and quality within the landscape, and (4) help mitigate the greenhouse effect by storing C in soil as organic matter. Literature in the southeastern USA was reviewed to illustrate the effect of improved pasture management on soil quality and soil organic C sequestration. Implications of soil organic C sequestration for provision of ecosystem services are discussed.

SPATIAL AND TEMPORAL VARIABILITY OF CO₂ FLUXES IN TEMPERATE PERMANENT GRASSLANDS ON PEAT SOILS

Schäfer Carolyn-Monika^{*[1]}, Elsgaard Lars^[1], Kutzbach Lars^[2], Petersen Søren O.^[1]

^[1]University of Aarhus ~ Department of Agroecology ~ Tjele ~ Denmark ^[2]University of Hamburg ~ Institute of Soil Science ~ Hamburg ~ Germany

Permanent grasslands constitute the most widespread land use type for agriculturally managed peatlands in Europe. They are typically significant sources of CO₂ to the atmosphere as a result of drainage-induced peat decomposition, but quantitative data are still scarce. This study presents the first in-depth analysis of CO₂ flux variability at the field and plot scale for different Danish grasslands on peat. Net ecosystem exchange (NEE) of CO₂ and ecosystem respiration were monitored over one year with temperature-controlled static chambers at a former bog with partly well preserved Sphagnum peat and at two fens with highly decomposed peat. The amplitudes of annual groundwater fluctuations were less than 40 cm at one of the fens and ~ 90 cm at the other two sites. The first part of the analysis consisted of a detailed evaluation of the flux dataset to gain insight into the effect of fast fluctuations (seconds to minutes) in the wind and light intensity on the plot scale CO₂ flux. In the second part of the analysis, gross photosynthesis and ecosystem respiration were modeled on the field and plot scale with candidate sets of simple light and temperature response models commonly found in the literature. The results of this analysis will be used to assess the influence of peat type, management intensity, vegetation cover and weather conditions on the spatial and temporal variability of CO₂ fluxes.

DUAL-CHAMBER MEASUREMENTS OF $\Delta^{13}\text{C}$ OF SOIL-RESPIRED CO_2 PARTITIONED USING A FIELD-BASED THREE END-MEMBER MODEL

Albanito Fabrizio*^[1], Mcallister Jonathan^[1], Robinson David^[1], Smith Pete^[1]

^[1]University of Aberdeen ~ Institute of Biological & Environmental Sciences, School of Biological Sciences ~ Aberdeen ~ United Kingdom

Reliably estimating the heterotrophic component of RS is crucial for the characterisation of an ecosystem's net C balance. However, the contribution of 'historical' soil C (SOM) to total soil respiration (RS) in forest remains still uncertain. One of the contributing factors of this uncertainty is the difficulty to reliably measure and partition key carbon-cycle processes. Isotopic methods, such as natural variations in carbon isotope composition ($\delta^{13}\text{C}$) of soil respiration, are more frequently being applied, and show promise in separating heterotrophic and autotrophic contributions to RS. In this study we report the partitioning of soil-surface CO_2 effluxes, measured in forests in Italy and in Germany, using a new field-based $\delta^{13}\text{C}$ method and a three end-member mixing model. Soil-surface CO_2 flux was partitioned into components derived from root, litter/humus and SOM sources, and compared this with the conventional partitioning into autotrophic and heterotrophic components (two end-member mixing model). In addition, we used a novel dual-chamber technique to ensure that measurements of $\delta^{13}\text{C}$ Rs were subjected to minimal artefacts during measurement. Our results provide new information about the contributions of belowground components to the CO_2 flux at the soil surface, and show an alternative approach to the partitioning of RS components using their ^{13}C signatures.

INCREASED CO₂ FLUXES UNDER WARMING TESTS IN HISTIC AND TURBIC CRYOSOLS FROM SALLUIT, NUNAVIK (QC, CANADA)

Fouché Julien^{*[1]}, Keller Catherine^[1], Ambrosi Jean Paul^[1], Allard Michel^[2]

^[1]Aix Marseille Université, CNRS, CEREGE ~ Département Sol, Eau, Déchets ~ Aix en Provence ~ France ^[2]CEN, Université Laval ~ Département de géographie ~ Quebec ~ Canada

Cryosols in tundra ecosystems contain large stocks of organic carbon. Global warming could induce an Arctic ecosystems positive feedback on global C release. Instrumentation was installed in Salluit (Nunavik; 62°14'N, 75°38'W) to monitor respiration of Cryosols under current and warmer conditions. Two experimental sites under tussock tundra vegetation were set up: one is a Histic Cryosol (organic soil, H site) in a polygonal peatland; the other is a Turbic Cryosol reductaquic (mineral soil, M site) on post-glacial marine clays. On each site an open top chamber was installed to modify thermal conditions in the active layer. All measurements were performed in both normal (N) and transformed (T) conditions from mid July to end of August 2010. At each site, surface temperature was monitored hourly and soil respiration (SR) was measured at 10:00 AM, 3:00 and 8:00 PM every second day with a respiration chamber linked to a portable IRGA. In natural conditions, average SR in H (0.96 $\mu\text{molCO}_2\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) was lower than in M (1.67 $\mu\text{molCO}_2\cdot\text{m}^{-2}\cdot\text{s}^{-1}$). An increase of the surface temperature of 2.5°C was observed and led to an 80% enhancement of SR at HT station. At MT station a 1.5°C increase induced an average SR increase of 40%. The induced warming increased CO₂ fluxes in both soils; this impact appears to be more striking in Histic Cryosols even if they have lower SR than Turbic Cryosols. SR variations at H and M sites follow the same seasonal trend, highly correlated with the surface temperature variations.

Our work focuses on the impact of climate change and human activities on the sensitive permafrost-affected geoecosystems on the Tibetan Plateau. We assume that permafrost dynamics are largely controlled by precipitation and temperature as well as land use changes and have a central impact on soil degradation, soil microbial activities and consequently on carbon sequestration, and greenhouse gas emissions. Our geoecosystem-based approach will determine carbon dynamics and greenhouse gas fluxes on three different spatial scales, namely landscape, plot and pedon. Soil temperature, soil moisture, and soil redox potential) are main drivers along the 1,500 km transect at altitudes between 4,600 and 5,100 m ASL. The allocation of 10 study sites along the permafrost transect includes different monsoon dynamics and thus, distinct temperature and moisture regimes. Our research is divided into (i) permafrost dynamics, pedogenesis and soil organic carbon stocks, variability and turnover, and (ii) formation of methane and carbon dioxide (methanogenesis and methane oxidation). The presentation will show results from the 2009 and 2011 expeditions integrating an indicator-based interpretation across scales from molecular biology to plot and landscape scale. Feedback mechanisms and the resultant risk potential related to material fluxes and greenhouse gas emission are of particular interest in the scope of a warming Earth.

**CHANGES IN AGROECOSYSTEM NUTRIENT STOCKS FOLLOWING AFFORESTATION OF
DEGRADED IRRIGATED CROPLAND IN CENTRAL ASIA**

Khamzina Asia^[1], Dubovyk Olena^[1], Lamers John P.a.^[1], Vlek Paul L.g.^[1]

^[1]University of Bonn ~ Center for Development Research (ZEF) ~ Bonn ~ Germany

Cropland degradation jeopardizes agro-ecosystem services in irrigated drylands of Central Asia, threatening economic development in the region. Climate change is likely to exacerbate the adverse effects via reducing water supplies for land reclamation and irrigation of water-intensive crops. This study in the downstream area of the Amudarya River addressed an adaptive option of setting aside degraded cropland for afforestation, to increase the land productivity and to mitigate climate change effects via creating carbon sinks. A spatio-temporal analysis based on MODIS NDVI images revealed that 36% of croplands (161,000 ha) in the area have experienced a vegetation decline, often associated with land abandonment. Carbon sequestration in small-scale, mixed-species tree plantations was monitored during seven consecutive years following afforestation. Depending on species potential, between 64 and 70 tC ha⁻¹yr⁻¹ was sequestered in woody biomass, of which roots accumulated 15-20 tC ha⁻¹. The increase in soil organic carbon (SOC) was most pronounced in the topsoil, ranging 7-12 t ha⁻¹. Without the forestry intervention, the abandoned cropland experienced a 30% SOC loss. Soil available N and P showed similar trends, with the fallow land measuring 1.5-2.5 times as little stock as the afforested plots. N₂-fixing species contributed the most to soil N, P, and SOC replenishment whereas exchangeable K increased regardless the species choice. The delineation of cropland parcels in need of rehabilitation, combined with field-observed nutrient accrual rates, indicate significant potential of afforestation as carbon sink in degraded cropping areas. Hydrological aspects are being analyzed to determine an appropriate scale of forestry decisions.

S06.02 -2

THE INFLUENCE OF ELEVATED AIR OZONE CONCENTRATION ON THE ENVIRONMENTAL BEHAVIOR AND ECOLOGICAL EFFECTS OF PYRENE IN SOIL

Guo Hongyan*^[1]

^[1]Nanjing University ~ School of the Environment ~ Nanjing ~ China

Pollution of the environment with both ozone and organic pollutants has been steadily increasing. Field studies on the synergic effect of these pollutants are limited. We studied the effects of elevated ozone on pyrene degradation in soil, bioaccumulation and oxidative stress on wheat using a free-air concentration enrichment (FACE) system. In this field experiment in Jiangdu (Jiangsu Province, China), wheat plants were grown in pots containing soil with various concentrations of pyrene (0, 100, and 200 mg kg⁻¹ pyrene was added to the soil) under ambient conditions and under elevated O₃ levels (50% higher than the ambient O₃) throughout the growth season. From 2008 to 2010, the concentration of pyrene in the soils decreased over time, and the concentration in ambient conditions were higher than that under FACE conditions. The concentration of pyrene in wheat tissues (shoots, seeds) exposed to elevated O₃ were higher than that in ambient conditions. With the concentration of pyrene increasing, the activities of APX, CAT, POD and SOD isoenzymes increased, and their activity in ambient conditions were higher than in FACE conditions, except in 200 mg kg⁻¹ treatment. In the future, pyrene will become easier to degrade with increased O₃ levels, but pyrene accumulation in wheat will still increase although the reason(s) for this increase remain uncertain. Thus, the synergic effect of these pollutants on the soil system may be more harmful to food safety in the future.

^[1]INRA ~ UMR FARE ~ Reims ~ France ^[2]INRA ~ UMR EGC ~ Grignon ~ France

Improving crop rotations, reducing or suppressing soil tillage, and maintaining a mulch of crop residues at the soil surface are gaining popularity throughout the world. But the impacts of these practices and of their combination on soil processes are not fully well understood. The objective of the work was to study, for different crop associations and pedo-climatic conditions met in temperate (France) and tropical (Madagascar and Brazil) agrosystems under conservation agriculture, the effects of residue mulch characteristics on their decomposition and subsequent fate of C and N in soil. An experiment was performed in controlled conditions with 10 cm wide x 25 cm depth soil columns. The treatments varied either by the type of residue mulch (mixture of Zea mais & Doliquos lablab or Triticum aestivum & Medicago sativa), or by the type of soil (sandy or loamy soil) and by the water regime (manipulated through the intensity and frequency of rain applied with a rain simulator to the columns). The incubation was performed at 20°C during 3 months with continuous measurements of CO₂, N₂O emissions and water dynamics, and with measurements of mulch, soil and microbial biomass C and N, by destructive samplings at 0, 14, 41 and 84 days. A C&N biotransformation and transport model coupled to a mulch module (Findeling et al., 2007) was tested and used to calculate fluxes that are not measureable (gross mineralization and immobilization, nitrate and soluble C leaching), and to extrapolate the fate of C on a longer term.

S06.02 -4

INTERACTION OF MITIGATION AND ADAPTATION STRATEGIES TO REDUCE GREENHOUSE GAS EMISSIONS FROM AGRICULTURE

Brilli Lorenzo^{*[1]}, Lugato Emanuele^[2], Moriondo Marco^[2], Ferrise Roberto^[1], Bindi Marco^[1]

^[1]Università degli studi di Firenze ~ DiPSA (Department of Plant, Soil and Environmental Science Section of Agronomy and Land Management) ~ Firenze ~ Italy ^[2]CNR ~ IBIMET ~ Firenze ~ Italy

In Italy, total greenhouse gas emissions (GHGs) from agriculture amounted to 34.5 Mt of CO₂ equivalent in 2009 (Romano et al., 2011), almost coming from N₂O emission from agricultural soils (15.5 Mt CO₂ eq.), manure management and enteric fermentation (6.6 and 10.7 Mt CO₂ eq.). In order to reduce these emissions and consequently impact on climate change, several mitigation strategies (MS), such as the use of less intensive or organic production systems, minimum tillage techniques and lower use of inorganic fertilizers, have been proposed (Lugato et al., 2010). However, these practices are generally not evaluated in combination with some adaptation strategies (AS) that farmers may adopt independently to offset climate change. In this work, a biogeochemical model (DNDC) was run to assess GHGs emissions in an intensive agricultural area of Tuscany region (Italy), for the present period (1976-2005) and in a projected warmer climate. A number of alternative MS with respect to conventional farming system have been compared, also in combination with potential farmer AS, in order to find the best combination of AS and MS for future periods. Model projections suggested that crop yield will increase under intensive management (on average 8% than present), as well as N₂O (+70%) and CO₂ (+35%) emissions. Simulation of MS resulted in a slightly reduced crop yield (-4%) and consistent lower N₂O emissions and N leaching (-70% and -67%, respectively) than intensive production system. The best combination of AS and MS was obtained using late cultivar and high rate of crop residue incorporation.

Applying manure leads to reduce chemical N fertilizer and to sequester carbon in soils. This study was conducted to quantify the effect of manure application on the CO₂, CH₄ and N₂O emission at five managed grasslands in four climatic regions in Japan. Net ecosystem exchange (NEE) by eddy covariance method, CH₄ and N₂O emissions by chamber method were measured at the plots of manure (M) and chemical N fertilizer (F) from 2004 to 2010. Manure application rate was decided based on the potassium demand of grasses. CO₂ emission was estimated as NEE – manure + harvest. Global warming potential (GWP) was calculated using conversion factors of 1 for CO₂, 25 for CH₄ and 298 for N₂O. CO₂ emission in F and M plots was 1.3±1.5 and -1.1±2.4 Mg C ha⁻¹ yr⁻¹, respectively, indicating that M plot gained carbon. Harvests in F and M plots were not different. NEE showed more CO₂ uptake in the F plot (-3.0±1.7 Mg C ha⁻¹ yr⁻¹) than in the M plot (-1.8±1.8 Mg C ha⁻¹ yr⁻¹), but manure carbon recovered the shortage. The small CH₄ uptake was found in the F and M plots (-0.03±1.2 and -0.15±0.4 kg C ha⁻¹ yr⁻¹, respectively). The significant N₂O emission was found in the F and M plots (4.2±3.6 and 4.9±3.7 kg N ha⁻¹ yr⁻¹, respectively). The GWP was significantly higher in the F plot than in the M plot. Harvest and N₂O emission increased GWP significantly, and NEE and manure carbon reduced GWP significantly.

^[2]Universidade Estadual Paulista ~ Soil Science ~ Jaboticabal ~ Brazil ^[3]Brazilian Agricultural Research Corporation (EMBRAPA) ~ Research and Development ~ Colombo ~ Brazil ^[4]University of Sao Paulo ~ Physics Institute of Sao Carlos ~ Sao Carlos ~ Brazil

Currently Brazil has in use to crops around 60 millions of hectares. Other 100 millions have potential to be increased from pastureland conversion or in combined use of crop and livestock productions, and yet some addition of new agricultural land in Savanna region, without any increase in deforestation of Amazon rainforest (around 85% preserved or 400 million of hectares). Conservative systems, as no-till, crop-livestock and crop-livestock-forest systems, have a growth adoption in Brazil with important potential of carbon sequestration. In all these systems spatial and temporal variabilities of soil carbon are crucial aspects so development of analytical tools to facilitate carbon content analysis is very important. Some laser-base methodologies, as laser-induced fluorescence spectroscopy (LIFS) and laser-induced breakdown spectroscopy (LIBS) are powerful alternatives for several quantitative and qualitative analysis of soil carbon. Results about carbon dynamics (soil carbon measurements with laser-based techniques and greenhouse gas emissions) in areas under sugar-cane cultivation, integration crop-pastureland and sewage sludge amendment in afforested areas will be presented showing complexity associated with these systems in different soils. For studied soils, preliminary results for integration crop-pastureland and sewage sludge addition systems promoted an increasing of soil carbon and a decreasing of humification degree of organic matter. This behavior is probably due to recent input of fresh organic matter. However, the continuous monitoring should provide more precise information about the dynamics of this soil carbon.

IMPACT OF CLIMATE CHANGE ON SOIL MICROORGANISMS AND CARBON CYCLING IN AN ARABLE ECOSYSTEM

Poll Christian^[1], Marhan Sven^[1], Niklaus Pascal^[2], Kandeler Ellen^[1]

^[1]University of Hohenheim ~ Institute of Soil Science, Soil Biology ~ Stuttgart ~ Germany ^[2]University of Zurich ~ Institute of Evolutionary Biology and Environmental Studies ~ Zurich ~ Switzerland

*Carbon cycling in terrestrial ecosystems provides a feedback mechanism to climate change by releasing or sequestering additional atmospheric CO₂. However, the role of soil microorganisms as key players in this feedback mechanism is still unclear. The Hohenheim Climate Change (HoCC) experiment was established in summer 2008 to manipulate soil temperature and precipitation on an arable field. Soil temperature is increased by 2.5°C in 4 cm and is combined in a factorial design with the following precipitation manipulation treatments: a) ambient, b) precipitation amount decreased by 25% during summer and increased by 25% during winter, c) drought periods increased by 50% during summer, d) combination of b and c. The experimental plots were planted with spring wheat (*Triticum aestivum*, 2009), spring barley (*Hordeum vulgare*, 2010) and oilseed rape (*Brassica napus*, 2011). Soil samples were taken at four occasions each year (March, June, August, November/December) in 0-5 cm, 5-15 cm and 15-30 cm depth. Data of aboveground biomass, soil organic carbon, soil microbial biomass and CO₂ fluxes (weekly measurements) will be presented. First results indicate that changes in soil temperature and precipitation differently affected aboveground biomass and that these effects depended on the crop. Effects of elevated soil temperature on microbial biomass and CO₂ fluxes were related to moisture conditions during the different seasons of the year. Overall, the presentation will give insight into the complex interactions between climate change, soil moisture and soil microorganisms as key players of carbon cycling in the investigated arable ecosystem.*

NUTRIENT AVAILABILITY AND UPTAKE UNDER DROUGHT CONDITIONS IN OAK MODEL ECOSYSTEMS WITH TWO DIFFERENT FOREST SOILS

Kuster Thomas M.*^[1], Patrick Schleppi^[2], Madeleine S. Günthardt-Goerg^[1], Rainer Schulin^[3]

^[1]Swiss Federal Research Institute WSL ~ Forest Dynamics ~ Birmensdorf ~ Switzerland ^[2]Swiss Federal Research Institute WSL ~ Forest Soils and Biogeochemistry ~ Birmensdorf ~ Switzerland ^[3]ETH Zurich ~ Institute of Terrestrial Ecosystems (ITES) ~ Zurich ~ Switzerland

Global climate change is expected to increase annual temperature and to decrease summer precipitation in Central Europe. Little is known on how drought, air-warming and their interaction affect forest soil fertility and nutrient uptake of trees. Therefore, we investigated the response in fertility of two forests soils, acidic and calcareous, stocked with young oak stands, to air-warming (+1-2 °C) and drought (-43% irrigation). Air-warming did neither change the nutrient availability nor their uptake. Possibly, soil temperature increase was too weak (+1 °C). Drought treatment increased the availability of Mg and P in the acidic soil, whereas no changes in NO₃⁻/NH₄⁺, K, Ca and Mn availabilities were recorded. Under drought, the concentrations of N and P in oaks growing on the calcareous soil increased whereas the concentrations of Mg and Ca decreased. Expectedly, soil reaction in well-watered calcareous (vs. acidic) soils resulted in lower P and Mn availabilities which consequently reduced the biomass of oak stands. However, under drought conditions there was no difference in biomass between the two soils, indicating that nutrient limitation was governed by water availability. In the acidic soil, oaks invested relatively more roots in the nutrient rich top layer than in deeper layers, whereas the root distribution in the non-layered calcareous soil was more uniform. Although drought effects on soil fertility and nutrient uptake were significant in this oak ecosystem study, the effects of water limitation on the oak stand performance were much more pronounced than the drought effects on soil fertility.

RESPONSE OF SOIL PROPERTIES TO A LONG TERM FACTORIAL SNOW AND N-FERTILIZATION EXPERIMENT, COLORADO FRONT RANGE, USA

Freppaz Michele^{*[1]}, Williams Mark W.^[2], Seastedt Timothy^[2], Filippa Gianluca^[1]

^[1]Università degli Studi di Torino ~ DIVAPRA - Laboratorio Neve e Suoli Alpini ~ Grugliasco ~ Italy ^[2]University of Colorado at Boulder ~ Institute of Arctic and Alpine Research and Department of Geography ~ Boulder ~ United States

Alpine ecosystems are thought to be particularly sensitive to small environmental changes in climate and other parameters due to the plants and soil organisms being on the edge of environmental tolerances. Snow distribution is critical to microclimate in the alpine, affecting soil temperature, growing season duration, and nutrient cycling. Moreover anthropogenic nitrogen deposition over the past half century has had a detrimental impact on temperate ecosystems, resulting in soil acidification and a reduction in plant biodiversity. Here we build on a snowfence experiment, combined with N-fertilization experiment, at the Niwot Ridge LTER site, to increase our understanding of how changes in snow properties and N deposition may affect soil processes. The snowfence used in this manipulation results in a pattern of snow accumulation, from deep snowpacks near the fence to moderate and shallow snowpacks away from the snowfence. Over the 16 years of the experiment, the amount, timing, and duration of snow cover appears to affect soil properties. Under the moderate snow cover, without N addition, a greater content of total organic carbon (TOC) and total nitrogen (TN) than either under deep or shallow snow was observed. Nitrogen amendments in general worked in the opposite direction of snowpack controls on soil processes. The N addition caused a significant increase under the shallow snow for TOC, and TN, while there was a significant decrease of these values under the moderate snow treatment. Our results clearly demonstrate how long-term changes in snow properties and N deposition may significantly affect soil properties.

EFFECTS OF LONG-TERM TEMPERATURE AND NUTRIENT MANIPULATION ON NORWAY SPRUCE FINE ROOTS, MYCORRHIZAL ROOT TIPS AND MYCELIA PRODUCTION

Leppälammi-Kujansuu Jaana*^[1], Ostonen Ivika^[2], Nilsson Lars Ola^[3], Berggren Dan Kleja^[4], Strömgren Monika^[4], Sah Shambhu^[1], Helmisaari Heljä-Sisko^[1]

^[1]University of Helsinki ~ Department of Forest Sciences ~ Helsinki ~ Finland ^[2]University of Tartu ~ Institute of Botany and Ecology ~ Tartu ~ Estonia ^[3]Norwegian University of Life Sciences ~ . ~ Ås ~ Norway ^[4]Swedish University of Agricultural Sciences ~ Department of Soil and Environment ~ Uppsala ~ Sweden

As fine roots are the main contributors in sequestering carbon into boreal forest soils, their responses to environmental changes, such as soil warming, are of great importance. We examined the responses of fine roots and mycelia production in a boreal Norway spruce (Picea abies (L.) Karst.) forest in northern Sweden after 14 years of soil warming and/or 22 years of liquid fertilization. The fine root biomass and necromass, ectomycorrhizal (EcM) root tip biomass, morphology and number, as well as mycelia production were determined. Total fine root biomass and necromass were the highest in fertilized plots, similar to the above-ground biomass, whereas warming increased the amount of fine root biomass and live/dead ratios deeper in the soil. Warming had a positive effect on the amount of EcM root tips in the mineral soil and tended to increase fungal mycelia production. Significantly higher specific root length of EcM tips revealed a possible stress reaction caused by warming, but in general fertilization affected the EcM root morphology the strongest. Consequently, changes in EcM root morphological traits reflected differences in foraging strategies of fine roots related to environmental conditions. Overall, through better nutrient supply and warmer soil temperature there is a potential to increase the flow of carbon to the soil via increased fine root biomass, but the carbon balance depends also on production and decomposition.

Future scenarios foresee more frequent and severe extreme events, such as heat wave and drought. Soil CO₂ efflux constitutes the second largest carbon flux between terrestrial ecosystems and atmosphere and derives from two main components, autotrophic respiration (Ra) being associated with root and rhizosphere respiration and heterotrophic respiration (Rh) associated with the turnover of soil organic matter by microorganisms. The aim of this work was to study how increased atmospheric CO₂ can mediate the effects of extreme events on grassland soil respiration and to analyze its components Ra and Rh. Grassland monoliths were exposed, from May 2010, to air temperature and precipitation expected for the period 2040-2060. Since March 2011 a CO₂ enrichment was applied and during summer a heat wave and drought stress was applied too. Soil respiration and its components were not significantly affected by elevated CO₂ until 4 months after the start of the CO₂ fumigation, but it increased under elevated CO₂ by about 20% during August and September. The extremes treatment decreased drastically soil respiration both at ambient (59%) and at elevated CO₂ (67%). Soil respiration recovered from extremes events, even if Ra and Rh showed different recovery times. This was associated to a recover of root growth and to an increase in root decomposition. This behavior agrees with preliminary data on daily ecosystem carbon uptake showing a stronger recovery after rewetting and under elevated CO₂ compared to ambient CO₂. In view of these results, the interactions between elevated CO₂ and extreme events will be discussed

CARBON AND NITROGEN DECOUPLING UNDER AN 11-YEAR DROUGHT IN THE SHORTGRASS STEPPE: IMPLICATIONS FOR INCREASED NUTRIENT LOSS AND PROLONGED ECOSYSTEM RECOVERY

Evans Sarah^{*[1]}, Burke Ingrid^[2]

^[1]Colorado State University ~ Graduate Degree Program in Ecology ~ Fort Collins ~ United States ^[2]University of Wyoming ~ Environment and Natural Resources Program, Dept. of Botany, Dept of Renewable Resources, and Program in Ecology ~ Laramie ~ United States

The frequency and magnitude of drought is expected to increase in the US Great Plains under future climate regimes. Although semiarid systems are often considered highly resistant to drought, novel drought events could alter linkages among biogeochemical processes, and result in new feedbacks that influence the timescale of ecosystem recovery. We examined changes in carbon and nitrogen cycling in the last two years of an 11-year drought manipulation in the shortgrass steppe, and under the first two years of drought recovery. We measured plant production, plant tissue chemistry, soil trace gas flux, and soil inorganic nitrogen pools to test whether drought decreased the nitrogen conservation in this ecosystem. We found soil inorganic nitrogen increased up to 4-fold under our most severe drought manipulation, but that this nitrogen may not have been accessible to plants and microbial communities under drought due to diffusion limitations. When plots received ambient rainfall under recovery, we observed higher plant tissue nitrogen and N₂O flux in drought plots, suggesting nitrogen use efficiency decreases and gaseous N-loss increases in the years following long-term drought. These changes in plant production and nitrogen cycling persisted up to 2 years after this 11-year drought. Our results suggest that an 11-year drought drastically alters biogeochemical and ecosystem dynamics in the highly drought-resistant shortgrass steppe. In semiarid systems, the more “open” nitrogen cycling we observed following severe drought could alter fundamental ecosystem properties and prolong, or prevent, recovery.

In 2010/2011 we installed a Network of Lysimeters in Germany & Austria. An amount of 142 "third generation lysimeters" delivers now up to 3800 Sensor signals continuously. Those are combined with fix and variable background information as well as with Meta data arriving from cameras, alarm systems, station management & maintenance inputs. They arrive at a database containing proofed, comparable & reliable long time measurements produced with standardized routines. In addition, modelled data as in situ retention curves or in situ evapotranspiration rates are available. Therefore, an automatized procedure for data upload, visualization, filter levels & backup's works in combination with comparable, modular & online accessible sensors, controllers and data loggers are in operation. The maintenance works at the field stations are based on the results of the data base. Beneath the site management the technical data management requires modern data acquisition and communication tools to ensure high quality, comparable and reliable long term data.

TERENO (TERrestrial ENvironmental Observatories) aims to collect and provide long-term observation data of the hydrosphere, biosphere, pedosphere, lower atmosphere, and anthroposphere across multiple spatial and temporal gradients. Based on the TERENO infrastructure, the lysimeter-network SoilCan a long-term large-scale experiment to study the effects of land use changes of terrestrial systems caused by Global Change, has been implemented and represents one of the key research infrastructures for pedological research in TERENO. Main objectives are the terrestrial hydrology, the N-/C-cycle and the biodiversity. In particular, the analysis of changes in water and matter fluxes in the soil-plant-atmosphere system is in the focus of SoilCan. The gained high-quality data will be used for the development and calibration of computer models in combination with remote sensing. The SoilCan network consists of 126 fully automated lysimeter systems that were installed at 13 highly equipped experimental field sites within the TERENO-observatories and the relevant status variables of each ecosystem are monitored (e.g. climate, hydrology, biosphere-atmosphere exchange, biodiversity, etc.). Lysimeters were either left at their sampling site, transplanted inside the observatory of origin, or moved within or between the four different observatories. The translocation of lysimeters was performed along existing temperature and rainfall gradients in order to simulate climate change. The lysimeters are currently cultivated as grassland or arable land with a standardized crop rotation of winter wheat – pea - winter barley - winter canola. The presentation will comprise the results and experience of 18 months of lysimeter networking and will give an outlook on future work.

LYSIMETER INVESTIGATIONS TO EVALUATE DROUGHT EFFECTS ON THE GROWTH REACTION OF TREES

Müller Jürgen^{*[1]}

^[1] Johann Heinrich von Thünen-Institute, Institute for Forest Ecology and Forest Inventories ~ Forest Ecology ~ Eberswalde ~ Germany

Broad areas of the northeast German lowlands are characterised by low precipitation and periods of summer drought. Scenarios of the climatic development for the next decades indicate an increase in weather extremes threatening the current ecosystems in their existence. In this region, forest hydrology research looks into the influence of differently structured forest on the landscape water balance. The use of different types of lysimeters in this region has a tradition of more than 100 years. A main topic of the research is to investigate the water consumption and the growth of the trees at decreasing water resources. To investigate the impact of intensified drought on forest regeneration field experiments were carried out with different types of lysimeters. This field laboratory enables investigations of the effects of drought on the growth and vitality of forest trees in the open under largely controlled conditions. Lysimeters with a surface area between 1m² and 100m² were installed in the open at ground level in isolation from the surrounding soil. Special lysimeters were fitted with an automatic retractable roof to eliminate precipitation from the site. The focus of the research is the investigation of growth reaction of trees and fine root development as a function of the soil water availability. The Forest structures with their special hydrological properties have a substantial influence on the water budget, water supply and water distribution. New technical developments as well as strategies for the lysimeter investigations will be presented and discussed.

IMPACT OF CLIMATE CHANGE SCENARIOS ON CROP YIELD, SOIL WATER AND NITROGEN BALANCE AT THE LYSIMETER SITE WAGNA, AUSTRIA

Klammler Gernot^[1], Fank Johann^[1], Kupfersberger Hans^[1], Draxler Johannes C.^[1]

^[1] JOANNEUM RESEARCH Graz ~ RESOURCES - Institute of Water, Energy and Sustainability; Water Resources Management ~ Graz ~ Austria

According to the IPCC (2007) future climate change scenarios suggest that global average temperature increases by 1.8 °C from 1980-2000 to 2100. This will result in increases in temperature, shifts in precipitation patterns, an increase in the frequency of flooding and droughts, and also water quality will be affected. Effects and implications on groundwater will depend on the groundwater system, and its geographical location. The goal of this work is to quantify the influence of climate change on groundwater recharge, nitrogen leaching and crop yields for the lysimeter site Wagna, Austria, using the unsaturated flow and transport model STOTRASIM. At this research station, the water movement and nitrate leaching below two lots have been monitored by two lysimeters over more than seven years. Lysimeter data have been used to calibrate STOTRASIM, which is applied for two future temperature and precipitation scenarios. These climate change scenarios rely on assumptions of certain economic and environmental future development and are gained by dynamical and statistical downscaling. On the one hand it is expected that a changing annual sum of precipitation does not influence the crop yield significantly, because the water storage capacity of the soil in Wagna is generally low, but will affect groundwater recharge and nitrogen leaching directly. On the other hand, higher future temperatures will probably increase crop yields and evapotranspiration in Wagna, which also influence groundwater recharge and nitrogen leaching. So the expected crop yield, groundwater recharge and nitrogen leaching will be affected by the combination of temperature and precipitation changes.

Lysimeters have mainly been used to investigate processes regarding soil hydrology and mass transport, but have rarely been utilized to study climate change effects of multi-trophic ecosystem processes and functions. In a multidisciplinary study, we tested the impact of a climate change scenario (longer dry periods, increased rainfall events) predicted for one of the most productive agricultural areas of Austria. Using the AGES Lysimeter station comprising 18 3-m² lysimeters we tested the effects of this climate scenario for the three major soil types of the region: calcareous phaeozem, gleyic phaeozem and calcic chernozem. We monitored soil hydrological and mass transport processes, chemical soil properties, emissions of greenhouse gases (CO₂, CH₄ and N₂O), soil microbial activity and soil faunal diversity. Furthermore, the impact on crop production (peas), root growth, rhizodeposition, mycorrhization and the establishment and diversity of weeds was assessed. The results of the first year of investigations will be presented, highlighting especially the integrated view of physical, chemical and biological processes in the soil plant system and its relevance for the development of mitigation and/or adaptation strategies. The soil type specific identification of the major drivers of observed changes will contribute to proposals for an ecologically sound management of the soils investigated. Ideas to extend the risk assessment area in conjunction with related projects in the EU region will be presented.

S06.04 -6

DO 59 YEARS OF HYDROLOGICAL AND HYDROCHEMICAL OBSERVATIONS ON THE 4 MEGALYSIMETERS NEAR CASTRICUM (NETHERLANDS) REVEAL EFFECTS OF CLIMATE CHANGE?

Stuyfzand Pieter Jan*^[1]

^[1]KWR Watercycle Research Institute ~ Water Systems ~ Nieuwegein ~ Netherlands

Bulk precipitation in the open field and the drainage water from four 625 m², 2.5 meter deep lysimeters, in coastal dunes of the Western Netherlands near Castricum, have been studied regarding their quantity and chemical composition. Each lysimeter is not weighable, contains a dendritic drainage system with a groundwater reservoir of maximum 0.25 m, and is filled with calcareous dune sand. Lysimeter 1 is barren, lysimeter 2 covered with dune shrubs (mainly sea buck thorn), lysimeter 3 with oaks and lysimeter 4 with black pines. In this contribution observations in the period 1941-1999 (from the beginning till the close down), are presented and interpreted with a focus on detecting effects of climate change. Since 1948 the addition of fertilizers to stimulate growth on the vegetated lysimeters has ceased, while growth of vegetation and thinnings have been well documented. Meteorological data reveal that during the whole study period mean annual temperature increased by about 1 °C, gross precipitation increased by 10-15% and wind velocity decreased by 15-20%. The time series of the drainage waters clearly show effects of differences in vegetation, growth of vegetation, trends in atmospheric pollution, extremes in rainfall and in sea spray deposition. These effects are largely overprinting any potential effects of climate change on the drainage quantity and quality of the 4 lysimeters, the occurrence of extremes in drainage and dissolved ions possibly excluded. Effects of increased gross precipitation and decreased wind velocities can be noticed in the bare lysimeter.

APPROACHES TO SOIL SUSTAINABILITY IN GUIDELINES FOR FOREST FUEL HARVESTING AND PRODUCTION IN FOREST AND PLANTATIONS

Stupak Inge*^[1]

^[1]University of Copenhagen ~ Forest & Landscape ~ Copenhagen ~ Denmark

There are concerns that forest fuel harvesting and production may decrease soil sustainability, due to its effects of soil physical, chemical and biological factors. The main issues are increased removal of soil organic matter, carbon and nutrients, soil compaction, and impacts of compensation fertilisation, e.g. with wood ash. An increasing number of countries have developed guidelines for sustainable harvesting and production of forest fuels. This paper analyses the approaches taken to ensure soil sustainability by such guidelines. Recommendations usually classify sites and stands according to the sensitivity to forest fuel extraction, and different types of restrictions are then imposed for a range of specific site types, for example the number of extractions during the rotation, types of extractions, share of material left in the single harvesting operation, spatial distribution of the left residues, use of compensation fertilisation, time for the nutrient removal and fertiliser addition in relation to the season and stand development stage. Differences between different countries are discussed in relation to the natural conditions and type of forestry

Canada's 10 provinces and three territories are responsible for forest management. Guidelines and regulations therefore differ across the country in response to local situations (site, land ownership, industry, regulatory history, politics). Intensive harvesting (whole-tree; WTH) began in the 1980s for economic reasons and usually predominates where it is applicable to local forest types and landscapes; resultant piles of harvesting residue (slash) at roadside can be of interest as a new source of biomass feedstock. In addition, previously non-merchantable trees are sometimes removed at final felling, which further reduces biomass previously left on-site; where trees are processed at stump, slash is sometimes (but not commonly) removed using second-entry systems. Governments developed sustainable forest management guidelines/regulations before the current interest in slash recovery, and there are a range of responses to new uses for biomass: some jurisdictions made no changes; some made no changes but summarized current practices in new explicit biomass policies; some instituted new biomass guidelines to enhance ecosystem protection; and one has (at least temporarily) banned whole-tree harvesting and residue removal for electricity generation from provincial land. The science that informs policy development has resulted in a range of policy responses, from new site-specific guidelines to use of spatially explicit nutrient cycling models for identifying sites that would be sensitive to intensive biomass removals. We will review the soil science that informs indicator development and the application of indicators in guidelines and regulations across Canada; we will also compare and contrast the situations in Canada and Europe.

**DEVELOPMENT OF FOREST BIOENERGY GUIDELINES FOR SOIL AND WATER
PROTECTION-EXPERETISE FROM UK**

Nisbet Tom*^[1]

^[1]Centre for Forestry and Climate Change ~ Forest Research ~ Alice Holt Lodge ~ Farnham, Surrey ~ United Kingdom

The development of forest bioenergy presents a number of risks to soil and water resources. Negative impacts include soil infertility, acidification, soil carbon loss, ground damage and diffuse water pollution. In addition, the potential high water use of Short Rotation Coppice and Short Rotation Forestry can reduce water resource availability and the maintenance of ecological flows in rivers. On the other hand, energy crops can provide a number of soil and water benefits, such as waste treatment, reduced nutrient and sediment delivery to watercourses, and the attenuation of flood flows. This presentation considers the development of guidelines to aid site selection and promote good practice for forest bioenergy in the UK. The principal policy instrument driving good forest practice is the UK Forestry Standard and supporting Forests and Soil and Forests and Water Guidelines. These define the standards and requirements for sustainable forest management and provide a basis for regulation and monitoring. The Guidelines include a number of measures designed to control risks and promote benefits associated with energy forestry. These will be described, along with separate guidance on site selection for harvesting residues and planting new energy crops.

**FOREST BIOMASS FOR ENERGY AND SUSTAINABLE MANAGEMENT OF FOREST SOILS –
WHAT DO WE NEED TO KNOW TO KNOW?**

Egnell Gustaf*^[1]

^[1]Swedish University of Agricultural Sciences ~ Forest Ecology and Management ~ Umeå ~ Sweden

The set targets for renewable energy use in 2020 within the European union will inevitably put more pressure on forest biomass within the union. In countries like Sweden and Finland this has already resulted in an increased harvest of nutrient rich forest biomass that used to be left in the forest during silvicultural operations oriented toward round-wood production for the forest industry. This has raised concerns about the sustainability in these practices when it comes to long-term site- and stand-productivity as well as soil acidity and quality of run-off water. Modeling approaches have suggested that in many cases it will not be sustainable to harvest nutrient rich forest biomass like logging residues, small diameter trees, and stumps with roots. This suggests that long-term site and stand productivity, soil quality, and surface water quality may be threatened by the new demand for forest biomass. Here we scrutinize uncertainties in models suggesting that bioenergy is a major threat to long-term site- and stand-productivity from losses with harvested biomass and leaching, to nutrients gained through weathering and deposition. The link between topsoil chemistry and surface water quality is also weak and needs further research before forest biomass for energy is disqualified as a sustainable alternative to fossil fuels. Furthermore, if needed, recycling wood ash to the forest soil could counteract many of the drawbacks with nutrient rich forest biomass for energy.

IMPACTS OF INCREASED BIOMASS USE ON SOIL SUSTAINABILITY IN AUSTRIA

Katzensteiner Klaus*^[1]

^[1]University of Natural Resources and Life Science (BOKU) Vienna ~ Forest and Soil Sciences, Institute of Forest Ecology ~ Vienna ~ Austria

Almost half of Austria is covered by forests. Incentives for the establishment of CHP plants have raised the demand for forest biomass dramatically during the last decade and lead to an increased utilization of small dimensions and forest residues. Opportunities and limitations for forest biomass utilization for Austria have been evaluated based upon data from the Austrian Forest Inventory, supporting soil information and nutrient balance modelling by the Research and Training Centre for Forests, Natural Hazards and Landscape. The application of the concepts at the scale of individual forest management units is however frequently restricted by missing site/soil information. Thus, guidelines are rarely applied due to a lack of data. To overcome these restrictions, novel methods for partly model based site classification are combined with forest growth and yield, carbon and nutrient balance models for test regions to estimate impacts of different utilization intensities on humus dynamics and nutrient budgets. The concepts will be presented, model results for contrasting site/soil situations (calcareous versus silicate parent material for soil formation) will be shown and possibilities for the application at regional scales will be discussed.

FOREST BIOENERGY AND SOIL SUSTAINABILITY IN THE UK

Vanguelova Elena^[1], Pitman Rona^[1]

^[1]Forest Research ~ Centre for Forestry and Climate Change ~ Farnham ~ United Kingdom

The ongoing drive to develop renewable energy is generating increasing interest in energy forestry in the UK. Woody biomass from both forest residues and short rotation forestry has the potential to make a significant contribution to climate change mitigation through fossil fuel substitution. However, there is a danger of practice running ahead of understanding of the environmental impacts and benefits. Consequently, there is an urgent requirement for scientifically underpinned guidance on best management practices to ensure soil protection, including sustaining forestry's key role in carbon capture. This presentation will address the main issues emerging from an expansion of energy forestry in the UK. It will focus on evaluating the impacts of forest bioenergy management practices on ground damage, soil fertility, acidification, carbon stocks and soil carbon sequestration potential. Impact of residue and stump removal on soil carbon and nutrient sustainability will be reviewed from long-term Whole Tree Harvesting (England) and Tree Stump Removal experiments in Scotland and Wales. Results from a review of the benefits and impacts of Short Rotation Forestry on ex-agricultural land to long term soil sustainability will also be presented. In addition, new bioenergy research studies and experimental monitoring networks in the UK will be described.

ASSESSING HARVESTING POTENTIAL AND NUTRIENT SUSTAINABILITY IN TEMPERATE FORESTS BASED ON MONITORING DATA

V.wilpert Klaus^[1], Bösch Bernhard^[2], Puhlmann Heike^[3], Zirlewagen Dietmar^[4]

^[1]Forest Research Institute Freiburg ~ Soil and environment ~ Freiburg ~ Germany ^[2]Forest Research Institute Freiburg ~ Biometry and Informatics ~ Freiburg ~ Germany ^[3]University Freiburg ~ Hydrology ~ Freiburg ~ Germany ^[4]INTERRA, Bureau for Environmental Survey and Research ~ Environment ~ Kenzingen ~ Germany

Actually an increasing demand on biomass harvest exists for regenerative energy production. Nutrient export will be predominantly high for fuel-wood harvest. Thus sustainability gets a crucial question. However nutrient export with harvest is not the only and unambiguously dominant threat for nutrient sustainability, since soils in Central Europe are widely afflicted by acid deposition. Thus the biomass potential as well as nutrient budgets must be reliably, and at landscape level quantified, in order to direct increased harvesting intensity in a responsible way and maintain soil sustainability. We present results of a study a growth-region in SW-Germany with 140.000 ha forests. We derived from National Forest Inventory (NFI) the harvested biomass and from Forest Environmental Monitoring (FEM), input with deposition and weathering, as well as exports with seepage and harvest. FEM data had to be transferred to NFI sites by means of regionalized maps, based on multiple linear regression models which predicted soil properties with landscape-related predictors, explaining around 70% of their variance. Following results will be presented: the enduring fuel-wood-potential corresponds to a permanent wattage of ca. 200 MW. The mean base-cation balance (Ca+Mg+K) displays without technical compensation a deficit of 0.3-0.6 kmolcha-1a-1, depending on harvesting strategy. Element budgets are available also for micro-nutrients. If nutrients would be quantitatively brought back to forest sites through wood-ash recycling, nutrient balances can be balanced. We developed an organizational strategy and a standardized product of a mixture between dolomite rock powder and wood-ash to be used for soil protective liming.

IMPACT OF SHORT- AND VERY SHORT-ROTATION COPPICES OF POPULUS AND SALIX SPECIES ON SOIL C, N AND P CYCLING

Guénon René^[3], Bastien Jean-Charles^[2], Thiebeau Pascal^[3], Bodineau Guillaume^[2], Bertrand Isabelle^[3]

^[1]French National Institute (INRA) ~ FARE ~ Reims ~ France ^[2]French National Institute (INRA) ~ UR AGPF ~ Orléans ~ France ^[3]French National Institute (INRA) ~ UMR FARE ~ Reims ~ France

The use of plant biomass appears as an interesting alternative to fossil fuel. Thus, it is necessary to develop and validate a so-called "second-generation" bioprocess for ethanol production by using lignocellulose. Within this context, Populus and Salix which are genus of fast growing trees may be suitable as bioenergy crops grown in short rotation systems. However, the effects of these woodfuel-production systems on soil fertility, quality and microbial properties have not yet been fully evaluated. The aim of this study was to investigate the impact of short- and very short-rotation coppices (SRC=5-8 and VSRC=2-3 years of rotation) on soil organic matter dynamics through C, N and P cycling. We used a field experiment located in the center of France (Saint-Cyr-en-Val), in which both species (one for each genus) were planted in May 2010. SRC were planted at a density of 1400 stems.ha⁻¹ while it was of 8000 stems.ha⁻¹ for VSRC. Two soil horizons were characterized i.e. 0-20 cm (tillage horizon) and 20-45 cm (deep horizon) and C, N and P exportations through biomass cut were measured while the amount of these elements remaining or returning to soil (roots and leaves) were quantified to approach the elemental balance of these crops. Our results indicate that, after only 2 years, Populus culture could affect the soil microbial status and soil organic matter content, especially at low density plantation (SRC) that could lead to resource erosion and decrease soil fertility on long term.

LOGGING RESIDUE AND STUMP HARVESTING AND FOREST SOIL SUSTAINABILITY IN FINLAND

Helmisaari Heljä-Sisko^{*[1]}, Kukkola Mikko^[2], Luiro Jukka^[1], Saarsalmi Anna^[2], Tamminen Pekka^[2]

^[1]University of Helsinki ~ Dept. of Forest Sciences ~ Helsinki ~ Finland ^[2]Finnish Forest Research Institute ~ Vantaa Research Centre ~ Vantaa ~ Finland

Forest soil is the basis for renewable forest resources, but the soil itself is practically non-renewable - only organic matter from above- and belowground litter slowly accumulates in forest soil. While long-term experiments exist for studying the effects of logging residue harvesting for bioenergy (Helmisaari et al. 2011), the use of stumps is a relatively recent phenomenon, and therefore long-term studies are rare. We report recent results on changes in forest soil sustainability on long-term logging residue experiments as well as on sites where stump harvesting was made 5-10 years ago in Finland. While the major effect on soil sustainability from logging residue harvesting is in the nutrient loss, followed by a decrease in tree growth, stump harvesting poses a threat to soil physical structure. After stump removal and site preparation, the share of undisturbed soil may account only around 30% of soil surface while site preparation alone may leave twice as large area untouched. The results are discussed in relation to present guidelines.

*Wildfire may cause significant changes to organic carbon stocks on the forest floor and in the topsoil. This may have important implications for the export of particulate and dissolved organic carbon from recently burnt forest areas, especially when considering the often-observed increases in runoff and erosion following fire and leaching from the ash/soil. Carbon losses by post-fire runoff, however, have been poorly studied in Mediterranean regions. The FIRECNUTS project (PTDC/AGR-CFL/104559/2008) aims to investigate, among others, the losses of organic matter and (in-)organic carbon by runoff in recently burnt areas, also in relation to topsoil stocks. The study area is located in north-central Portugal. It was burnt by a wildfire in the summer of 2010, affecting some 250 ha of forest plantations of Maritime Pine (*Pinus pinaster*) and especially eucalypt (*Eucalyptus globulus*). Monitoring began before the occurrence of significant rainfall and has since been carried out at regular intervals (at 1- to 2-weekly intervals), both in microplots (0.28 m²) and at the slope scale (83-170 m²). (In-)organic carbon was analyzed using a Shimadzu TOC Analyser. This presentation will focus on the results for dissolved (in-)organic carbon content of the runoff generated during the first year following the wildfire. Higher concentrations were found in burnt pine stands when compared with burnt eucalypt stands, which is possibly due to differences in post-fire litter cover from scorched leave/needles and/or to differences in runoff rates. Concentrations decreased with time at all study sites, pointing to the exhaustion of the carbon stock available for export.*

CAN MOLECULAR MARKERS FOR PYROGENIC CARBON HELP TO RECONSTRUCT WILDFIRE TEMPERATURES?

Schneider Maximilian P.w.^{*[1]}, Hockaday William C.^[2], Masiello Caroline A.^[3], Schmidt Michael W.i.^[1]

^[1]University of Zurich ~ Department of Geography ~ Zurich ~ Switzerland ^[2]Baylor University ~ Department of Geology ~ Waco, Texas ~ United States ^[3]Rice University ~ Department of Earth Sciences ~ Houston, Texas ~ United States

The maximum temperature experienced by charcoals strongly influences relevant properties, such as sorption capacity and degradability. Yet information about the formation temperature of natural charcoal is difficult to obtain. Benzenepolycarboxylic acids (BPCA) are molecular markers specific for pyrogenic carbon (PyC) and are used to quantify PyC in soils, sediments and oceans. Additionally to quantitative information, BPCA provide information on the degree of aromatic condensation in charcoals. We calibrated this “molecular thermometer” by using a thermosequence of charcoals produced at temperatures from 200 to 1000°C under controlled laboratory conditions. So far it is not clear how other factors during pyrolysis, such as availability of oxygen, moisture and exposition time, influence the resulting molecular marker pattern. Here we apply the molecular marker method to a set of 10 charcoals produced during a controlled burn experiment, which was conducted at the US Forest Service Silas Little Experimental Forest, located near New Lisbon, New Jersey. The charred samples were derived from litter and bark of pitch pine and inkberry plants. Thermo-sensitive paints were used to keep record of the maximum temperature that a sample experienced during the fire event. Maximum temperatures of 260 to 650°C were monitored, which are typical temperatures for wildfires and which is well within the calibrated temperature range of the thermosequence charcoals. We compare the estimated formation temperatures derived from molecular marker patterns with those measured by the thermo-sensitive paints. Our results show if the “molecular thermometer” can be used to estimate the formation temperature of natural charcoals.

APPLICATION OF THERMAL AND SPECTROSCOPIC TECHNIQUES TO ASSESS THE STABILITY OF PYROGENIC ORGANIC MATTER IN A BURNT FOREST

Mastrolonardo Giovanni^[1], Francioso Ornella^[2], Di Foggia Michele^[3], Bonora Sergio^[3], Certini Giacomo^[1]

^[1]Università degli Studi di Firenze ~ 1Dipartimento di Scienze delle Produzioni Vegetali, del Suolo e dell'Ambiente Agroforestale (DIPSA) ~ Firenze ~ Italy ^[2]università di Bologna ~ 3Dipartimento di Scienze e Tecnologie Agroambientali ~ bologna ~ Italy ^[3]università di Bologna ~ Dipartimento di Biochimica ~ bologna ~ Italy

Fire events generally are considered as a major disturbance factor in forest ecosystems. The high temperatures may irreversibly alter physical, chemical, and biological soil properties. Fire can totally oxidise soil organic matter (SOM), however, under environmental conditions, the combustion is often incomplete, leading to formation of rearranged macromolecules, with prevailing aromatic nature and characterised by marked recalcitrance to degradation. In a burnt pine forest in Tuscany, Central Italy, we sampled the charcoal layer formed onto the ground and the top ten cm of mineral soil. The latter and the litter layer were sampled in an adjacent unburnt area similar to the burnt one prior to the wildfire occurrence. The aim of our work was to evaluate, combining thermal and spectroscopic analyses, how much fire may influence the biogeochemical stability of SOM. The composition of the intact litter, the charcoal on the ground and the SOM from the mineral soil were analysed by attenuated total reflectance/Fourier transform infrared (ATR/FT-IR), solid-state ¹³C nuclear magnetic resonance (NMR) spectroscopy, thermogravimetric (TG-DTG), and differential scanning calorimetry (DSC) analysis. Such analytical techniques were used to assess the effect of fire at molecular level, so as to infer the thermal and biochemical stability of the investigated organic pools. Overall, our findings showed that the wildfire, although of moderate intensity, had modified tremendously the chemical structure of the residual SOM, making it little appetizing to the heterotrophic organisms and, hence, able to stay for a long time in soil.

Transformation of monomeric organic substances in soil is an important process in soil, as all high molecular substances pass this stage during decomposition. Using organic monomers as biomarkers requires their unmodified stabilization, but microbial transformation of lipid biomarkers is hardly investigated. We assessed transformations of palmitic acid by injecting position-specifically labeled ¹³C-palmitate into soil. Microbial utilization was quantified by chloroform-fumigation-extraction. ¹³C-PLFA revealed utilization and transformation of palmitic acid by microbial groups. After ten days, the maximum of palmitic acid incorporation into microbial biomass (<10% of added label) and PLFA (<0.1%) was not reached, yet. The C1-group was preferentially decarboxylated. Incorporation was highest in 16:0-PLFA, as 16:0-fatty acid is a lipid precursor in metabolism, but transformation to a broad range of microbial fatty acids was detected. Position-specific labeling and its coupling with compound-specific analyses allow conclusions about the mechanisms and kinetics of microbial utilization and reveals transformation of biomarkers in soils.

DEVELOPMENT OF A NOVEL TOOL FOR SOIL SCIENCE BASED ON COMPOUND-SPECIFIC DELTA18O ANALYSES OF (HEMI-)CELLULOSE-DERIVED MONOSACCHARIDES

Tuthorn Mario^{*[1]}, Bruno Glaser^[2], Michael Zech^[4]

^[1]University of Bayreuth ~ Department of Soil Physics and Chair of Geomorphology ~ Bayreuth ~ Germany ^[2]Martin-Luther University Halle-Wittenberg ~ Department of Soil Biogeochemistry ~ Halle ~ Germany ^[3]Martin-Luther University Halle-Wittenberg and University of Bayreuth ~ Department of Soil Biogeochemistry ~ Bayreuth ~ Germany ^[4]Martin-Luther University Halle-Wittenberg and University of Bayreuth ~ Department of Soil Biogeochemistry, Department of Soil Physics and Chair of Geomorphology ~ Halle and Bayreuth ~ Germany

Compound-specific stable carbon, nitrogen and hydrogen analyses of molecules extracted from soil organic matter have become invaluable tools in soil science and paleoclimate research, respectively, during the last approximately 15 years. By contrast, although technical improvements allow the coupling of gas chromatographs with isotope ratio mass spectrometers via online pyrolysis reactors (GC-Py-IRMS) also for 18O analyses this technique is hardly applied by researchers, so far. We see large potential for this method in soil science, especially when combined with palaeoclimate research, because it is well known that not only deltaD, but also delta18O of precipitation and of certain chemical compounds of plants (e.g. cellulose) depend on climate parameters. In a first analytical step, we extract hydrolytically from soil, sediment or plant samples the monosaccharides such as arabinose, fucose, xylose and rhamnose. In a second analytical step, we derivatise the monosaccharides, thus making them GC-amenable. Compound-specific delta18O measurements are finally carried out using GC-Py-IRMS (Zech, M. and Glaser, B., 2009, RCMS 23, 3522-3532). Theoretical considerations and experimental results demonstrate that oxygen exchange reactions do neither occur to (hemi-)cellulose monosaccharides in natural archives nor during our analytical workup (Zech et al., 2011, OrgGeochem, in press). First results from applications of the novel method are presented for a 240 ka paleosol sequence in NE-Siberia and for Late Glacial and Holocene high mountain lake sediment cores from Helambu Himal, Nepal. Accordingly, delta18O variations of hemicellulose sugars reflect the two last glacial-interglacial cycles and record the variability of the Indian Summer Monsoon, respectively.

HYDRATION OF SUPRAMOLECULAR SOM STRUCTURE: THE COOPERATIVE RESPONSE OF SORBATE-SOM INTERACTIONS AND THE POSSIBLE ROLE OF ORGANIC SORBATE SIZE

Borisover Mikhail^[1], Sela Maggie^[1], Chefetz Benny^[2]

^[1]The Volcani Center, Agricultural Research Organization ~ Institute of Soil, Water and Environmental Sciences ~ Bet Dagan ~ Israel ^[2]The Hebrew University of Jerusalem ~ The Department of Soil and Water Sciences, the Faculty of Agriculture, Food and Environment ~ Rehovot ~ Israel

Soil organic matter (SOM) controls distributions of multiple organic compounds between different environmental compartments. The role of SOM-associated water in sorbate-SOM interactions is not well understood, in contrast to the role of solute-bulk water interactions. Supramolecular SOM structure presumes a complexed response of organic sorbate-SOM interactions to the SOM hydration. Therefore, the SOM-associated water may affect organic compound – SOM interactions in a cooperative manner. This becomes evident as the power function increase in organic compound sorption with increasing water activity. Such a cooperativity reflects a participation of several solvent molecules in disruption of multiple interactions in the supramolecular SOM structure. Using the data on sorption of organic compounds on the differently hydrated organic matter-rich peat chosen as a model SOM sorbent, this paper examines the cooperative involvement of water in interactions between SOM and one probe organic sorbate, carbamazepine (CBZ), and compares it with the earlier studied phenol-SOM interactions. In comparison with a smaller-size organic sorbate, CBZ needs more SOM-associated water in order to demonstrate the strengthening of interactions with SOM, and, when started, this strengthening rises more steeply with water activity. Therefore, for penetration of the larger sorbate molecules into the SOM interior, a greater number of water molecules are needed to compensate for the local SOM disintegration thus suggesting the greater extent of the cooperativity in the involvement of water molecules in the organic compound-SOM interactions. This comparison provides an insight into the significance of the structural organization of SOM for its potential to sequester organic molecules.

Carbon from biodegradable organic compounds in soil divides into parent compound, metabolites, non-extractable residues (NER), CO₂, and microbial biomass. This distribution must be considered for assessing the compound fate in soil. The formation and composition of soil organic matter (SOM) or humic compounds is a long lasting topic in soil science but the processes are still not yet understood. For decades, humic substances were considered as a novel category of cross-linked organic materials. However, recent results identified microbial biomass as a significant source for SOM. Using ¹³C-labelled bacterial cells incubated in agricultural soils and tracing the fate of the label of bacterial biomass components in soil, a high percentage of the biomass carbon remains in the non-living SOM. These residues could be visualised by scanning electron microscopy (SEM) as fragmented bacterial cell walls debris of 200-500 nm size in various stages of decay and fragmentation. The results provide a simple explanation for the development of nano-scale patchy organic materials observed in soil SEM/TEMs. In addition to small plant debris, microstructures of microbial cell wall debris and thus provide the molecular architecture of SOM. This origin and macromolecular architecture of SOM is consistent with most observations on SOM, e.g. the abundance of biomarkers, the low C/N ratio, the water repellency, the stabilisation of biomolecules, and the formation of some NER from pesticides. This was confirmed by analyzing the NER from several labeled pesticides in soil, which indicates that virtually all of the NER of the compounds are derived from microbial biomass.

Various fractionation schemes and chemical extraction methods have been developed to quantify and qualify soil organic matter (SOM) and are reported in the literature. Hence, various procedures exist to isolate e.g. labile and recalcitrant fractions of SOM. However, only few studies explored the properties and the comparability of fractions obtained by different methods. This study compares two fractionation methods, i.e. density fractionation by sodium polytungstate SPT (Na₆(H₂W₁₂O₄₀)) and chemical fractionation by sodium hypochlorite (NaOCl). In particular, the focus is on the comparison of the mineral fraction (>2.0 g/cm³) gained from density fractionation with the respective NaOCl fraction. To investigate this even further, density fractions >2.0 g/cm³ were additionally treated with NaOCl. It is hypothesised that both methods identify the same recalcitrant fraction of SOM in different soil samples. Furthermore, quantitative parameters such as total carbon (C_t) and total nitrogen (N_t) have been determined. Spectra of Fourier-Transform-Infrared-Spectrometry (DRIFT-FTIR) and of pyrolysis-field ionisation mass spectrometry (Py-FIMS) of all fractions have been recorded. Results show that the chemical characteristics of fractions, although conformally defined as the stable, recalcitrant fraction, differ widely depending on the fractionation method used. Other than SPT density fractionation, NaOCl as a highly oxidative agent tends to eliminate specific chemical components of SOM. The combination of data from FTIR and Py-FIMS analyses provides detailed information on these changes.

USEFULNESS OF ^{31}P NMR TO ELUCIDATE PHOSPHATE-METAL-HUMIC COMPLEXES IN COMPLICATED MINERAL AND ORGANO-MINERAL MATRIXES

Baigorri Roberto^{*[1]}, Urrutia Oscar^[1], Erro Javier^[1], Mandado Marcos^[2], García-Mina José María^[1]

^[1]Timac Agro Int-Roullier Group ~ R&D Department (CIPAV) ~ Orkoien ~ Spain ^[2]University of Vigo ~ Physical-Chemistry Department ~ Vigo ~ Spain

Phosphate-Metal-Humic complexes play an important role in the interaction between soil solution and root system in the rhizosphere. Thus, the characterization of these complexes in complicated matrixes is very important and some authors have applied ^{31}P NMR to characterize Phosphate-Metal-Humic (PMH) complexes. They observed that the complexation process was related to significant changes in the width of phosphate-related peak. These authors associated this broadening with distortion effects on the coordination sphere of phosphate by humic-binding sites through metal bridges. In this work, we have applied ^{31}P NMR to study the formation of PMH complexes in two closely-related, but different fertilizer matrixes: Single super-phosphate (SSP) and Triple super-phosphate (TSP). Before carrying out these studies, we confirmed both the theoretical chemical viability and the complexing binding process by using Molecular Modelling and Fluorescence Spectroscopy. The ^{31}P NMR revealed that this technique may be useful to characterize PMH complexes. However, the data interpretation is not as clear as it was proposed in previous works. Our experiments showed that complex formation has different effects on phosphorus-related peak distribution and features, depending on the mineral matrix (SSP or TSP). We observed that complex formation causes an increase in the width of the peak associated with monocalcium phosphate in SSP matrix whereas in TSP matrix the effect was just the opposite, a decrease in the width of this peak. We discuss these results and propose a hypothesis to explain these differences in ^{31}P NMR spectra associated with PMH complex formation in SSP and TSP fertilizer matrixes.

Macromolecules are synthesized by Biota for structural scaffolding, metabolic reservoir, catalytic activity or conservation and expression of genetic information. It is significant that Biochemistry prefers formation of reversible bonds between small building blocks in synthetic pathways of biomacromolecules. Chemical compliance to this approach is nowadays desirable, in order to moderate environmental impacts. The research of such a synthetic strategy has brought a new concept in chemical synthesis: "Click Chemistry". For a reaction to comply with Click approach it is required: i. high yields ; ii. favourable kinetics; iii. mild reaction conditions; iv. absence of toxic byproducts; v. cost efficiency of reagents and vi. compatibility with water solutions. In an attempt to modify soil humic substances with a "Click Chemistry" approach, an alkynyl alcohol was esterified with carboxyl groups of an organosoluble fraction from peat humic acid through ester formation. The freshly introduced triple bonding was then conjugated with a hydrophilic azidoamine via 1,3 dipolar cycloaddition. The result was a humic molecule with improved hydrophilicity and positive ionizability. The adducts were characterized via HPSEC hyphenated to Electrospray-Orbitrap Mass Spectrometry. Several formulae were found attributable to Click products from short (C8) and long chained (C>20) carboxylic acids, albeit with low yields. Surprisingly, humic molecules conjugates of average length (C16-18) were not observed. Tandem MS was also used for structural clarification and rule out amine-ester transposition. We showed a Click chemistry application for cheap, easy, and flexible modification of humic substances and may represent an advanced supramolecular engineering for soil humic matter.

EFFECT OF TEMPERATE ALLEY CROPPING SYSTEM ON SOME SOIL PROPERTIES IN SOUTH EASTERN TURKEY

Gundogan Recep^[1], Sarikoc Mustafa^[1], Demirkiran Ali Riza^[2], Erol Adem^[3], Merdun Hasan^[4]

^[1]Kahramanmaraş Sutçu Imam University ~ Soil Science and Plant Nutrition ~ Kahramanmaraş ~ Turkey ^[2]Bingöl University ~ Soil Science and Plant Nutrition ~ Bingöl ~ Turkey ^[3]Kahramanmaraş Sütçü Imam University ~ Crop Sciences ~ Kahramanmaraş ~ Turkey ^[4]Akdaniz University ~ Department of Environmental Engineering ~ Antalya ~ Turkey

Intensive tillage and erosion lead to soil degradation in Pistachio orchard on slopping area in South east Turkey. Although it is not widespread practice because of concern of severe competition for water and nutrients, barley and legumes are grown for grain and forage production between pistachio and olive orchard in southeast Turkey. The study was carried out in an alley cropping system with forage crops (vetch, barley and vetch barley mixture) and Pistachio in 2008 to 2011 at South East. Soil properties includes soil organic matters, particle size, agregat stability, pH, CEC, total nitrogen are sampled at 0-15 cm depth and prior to seedling and after harvesting every year. The results show that there were no statistical differences between control and forage crops treatments. This study suggests that alley cropping effect on soil properties do not reveals in through three-year treatments. So these works should be extend much more year in order to reveal the plants effect on soil properties.

METABOLIC PROCESSING OF N AND C FROM INDIVIDUAL AMINO ACIDS AND WHOLE DUNG: A COMPOUND-SPECIFIC DUAL STABLE ISOTOPE PROBING APPROACH.

Knowles Timothy^{*[1]}, Chadwick David^[2], Bol Roland^[2], Evershed Richard^[1]

^[1]University of Bristol ~ Organic Geochemistry Unit, School of Chemistry ~ Bristol ~ United Kingdom ^[2]Rothamsted Research, North Wyke ~ North Wyke ~ Okehampton ~ United Kingdom

The availability of biologically accessible forms of N influences the diversity, dynamics and functioning of many ecosystems including soils. Organic N represents the vast majority of natural N inputs to soils and of these, proteins, peptides and amino acids are the most significant. A grassland soil was incubated with dual ¹⁵N,¹³C-labelled substrates (glutamate, glycine and cow dung) in separate incubations, enabling the fate of their N and C to be followed independently over a time course (between 3 h and 32 d). A molecular level approach was adopted throughout, whereby chemically and isotopically defined substrates were added to soil before isotopic analyses of individual soil amino acids, respired CO₂ and bulk soil. Compound-specific N and C isotope analyses of soil amino acids after the addition of individual amino acid substrates revealed highly conservative biochemical processing of these substrates by the soil microbial community. Moreover, a significant decoupling of the soil N and C cycles was demonstrated at the amino acid level, whereby the disparate fates of C and N from substrates in which they were covalently linked are clearly apparent. This approach was extended to investigations into the physical transport and biochemical transformations of dung-derived N and C after its addition to soil. Results revealed valuable information regarding the transport processes involved in dung matter incorporation into soil and significantly, the chemical forms in which it is transported and biochemical fate once within the soil.

COMBINING ANALYTICAL TECHNIQUES FOR SOIL ORGANIC MATTER CHARACTERIZATION IN THE FRENCH PREALPS: PARTICLE-SIZE FRACTIONATION, ROCK-EVAL PYROLYSIS AND MID-INFRARED SPECTROSCOPY

Saenger Anais^[1], Cecillon Lauric^[1], De Danieli Sebastien^[1], Brun Jean-Jacques^[1]

^[1]CEMAGREF ~ Mountain Ecosystems ~ Grenoble ~ France

Our objective was 1/ to characterize soil organic matter (SOM) under different land uses in the French calcareous Prealps by comparing three analytical approaches: the particle-size fractionation of soil organic matter, the Rock-Eval pyrolysis and the Fourier transform mid infrared (FT-MIR) spectroscopy and 2/ to relate structural characteristics of SOM to soil properties. We sampled the humiferous episolum (0-6 cm depths) on 127 sites including coniferous forest, mountainous grasslands and alpine meadows in the Vercors Regional Park during summer 2009 and 2010. The Rock-Eval pyrolysis opens interesting prospects for soil science but surprisingly its application remains very limited. This technique provides valuable information on the bulk composition and the stage of maturation of SOM and brings us to discuss the concept of recalcitrance for SOM stabilization. The particle-size fractionation (Feller, 1979) gives access to SOM pools and allows discussing the importance of physical protection mechanisms for SOM stabilization. The FTIR spectroscopy method brings precious insights on the chemical composition of SOM in these different fractions. We conclude that these techniques are very complementary and provide information at varying angles on the quality and dynamics of SOM in these mountain ecosystems.

This study aimed to address the question of whether or not there are preferred sites of sorption of organic compounds to soil organic matter (SOM) on the basis of functional group chemistry and/or domain character. C-CP/TOSS NMR spectra were acquired for stable nitroxyl free radical probes, HTEMPO (1-oxyl-2,2,6,6-tetramethyl-4-hydroxypiperidine) and TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) sorbed to Pahokee Peat (Florida), the soft coal Beulah Zap lignite (North Dakota), and polystyrene-polyvinylmethylether (PS/PVME), a 50:50 polymer blend homogeneous on the 1 nm scale. Polydimethylsilane was used as an inert internal standard. These probes interact through van der Waals and weak H-bonding forces and induce relaxation due to strong electron-nuclear spin interactions. The result is attenuation of ¹³C signal that is within 1 nm radius of the sorbed molecule. Titration of the solids with spinprobes, therefore, reveals preferential sorption sites by the concentration rate of change of signal suppression. With SOM or PS-PVME we find little to no selectivity for probes on the basis of functional group identity (polymethylene, polar aromatic, nonpolar aromatic, polar aliphatic, carboxylic) indicating that the composition of SOM surrounding individual sorbed molecules is, on average, fairly homogeneous. Furthermore, the small black carbon content of these samples appears not to play a strong role in sorption. Thus, site selectivity more likely is a function of the thermodynamic physical state of SOM vis the configurations and conformations of the SOM strands at the microstructural level. This work demonstrates for the first time the use of free radical molecular probes to study sorption specificity.

ONE AND TWO DIMENSIONAL SOLID STATE NMR TECHNIQUES APPLIED TO STUDY THE STRUCTURE AND RIGIDITY OF SOIL ORGANIC MATTER (SOM)

Jäger Alexander^{*[1]}, Bertmer Marko^[1], Schaumann Gabriele E.^[2]

^[1]Universität Leipzig ~ Fakultät für Physik und Geowissenschaften ~ Leipzig ~ Germany ^[2]Universität Koblenz-Landau ~ Institut für Umweltwissenschaften ~ Landau ~ Germany

With solid state NMR experiments, carried out on soil samples using one and two dimensional static and magic angle spinning (MAS) techniques, one can obtain various types of information on soil organic matter (SOM) such as chemical structure, soil rigidity or interaction of soil components with water. A main focus of our work are effects of water network disruption, making use of a $1H$ wide line decomposition scheme that straightforwardly yields results on the amount of water in hydrogen bonding networks. Different soils as well as variations due to atmospheric humidity, cation content with different valency, and temperature can be identified and the long term behaviour can be followed in a time range of weeks to months. To overcome the limited resolution of $1H$ MAS spectra, we apply advanced 2D phase modulated Lee-Goldburg (PMLG) $1H$ - $1H$ correlation experiments on soils to identify and quantify signals of different functional groups in short time and identify interactions between functional groups via exchange experiments. In ^{13}C NMR spectra we focus on the temperature dependence of poly(methylene) signals coming from two conformations, trans and gauche. After temperature treatment of soil, differences caused by the cooling procedure have been observed afterwards, that are to some extent in contradiction to observations for pure polymers. Finally, ^{27}Al MAS and MQMAS (multiple-quantum) NMR spectroscopy can identify clay formations such as montmorillonite or kaolinite. But more so we are interested in the effects of cations within the water-bonding network where Al^{3+} ions are supposed to act as mediators between water molecules and SOM segments.

NMR is a key method to characterize environmental species on a molecular level. We present several examples how insights into soil processes can be obtained using new NMR approaches. Frozen soils still emit greenhouse gases, but these emissions cannot yet be modeled. Using 2H NMR (Sparman et al ES&T 2004) to quantify the remaining liquid water in frozen soils, we can separate the influences of water availability and of the biochemical temperature response on CO₂ evolution (Öquist et al GCB 2009). Incubating soils with 13C-labeled substrate and detecting the label by 13C NMR, we demonstrate that microbial metabolism under frozen conditions is slower but otherwise not significantly different from unfrozen conditions (Öquist et al PNAS 2010). Phosphorus is of paramount importance for productivity in natural ecosystems and agriculture. Organic P species constitute a major fraction of soil P, but little is known about their turnover and bioavailability. Commonly used 31P NMR can often not resolve individual phosphomonoesters. We demonstrate how 2D NMR can be developed to unambiguously identify organic P species (submitted), allowing to define sources and determinants of bioavailability of individual P species (Vincent et al Biogeochemistry 2011). Intramolecular distributions of stable heavy isotopes, measured by NMR, are powerful tools to define plant metabolic fluxes (Augusti et al New Phytol 2006), and allow reconstruction of climate and physiological signals over centuries (Augusti et al Chem. Geol 2008). Based on the same principles, we will present a new approach to identify sources of soil constituents, and to elucidate their turnover.

COMPREHENSIVE MULTIPHASE NMR: A POWERFUL NEW APPROACH FOR UNDERSTANDING CONTAMINANT SORPTION AND SEQUESTRATION IN WHOLE FULLY SWOLLEN SOILS

Courtier-Murias Denis^[1], Longstaffe James G.^[1], Soong Ronald^[1], Botana Adolfo^[1], Farooq Hashim^[1], Masoom Hussain^[1], Simpson Myrna^[1], Simpson André J.^[1]

^[1]University of Toronto ~ Department of Chemistry ~ Toronto ~ Canada

Contaminants can persist and accumulate in the terrestrial environment as they tend to strongly associate with soil organic matter. The success of current remedial strategies is impeded by an incomplete understanding of the mechanisms of their sorption and sequestration. One of the obstacles to a better understanding is the reality that soils contain liquid-, gel- and solid-like phases and that it is the combined effects of these phases that determine their environmental properties. Studying each phase separately can perturb the sample, therein removing important chemical information about the gel-solid interface, kinetics across phase boundaries, and conformation in the natural state. Here, a newly developed Nuclear Magnetic Resonance (NMR) hardware termed Comprehensive Multiphase (CPM)-NMR Spectroscopy is described. CMP-NMR combines all aspects of solid-state, liquid-state and gel-phase NMR (HR-MAS) into a single NMR probe permitting all bonds in all phases in an intact and unaltered sample to be observed. Using Comprehensive Multiphase (CPM)-NMR Spectroscopy signals from liquid-, gel- and solid-like phases can be differentiated in whole soils. Contaminants that do not bind to soil can be studied using T2-filtered and “inverse” diffusion editing (DE) experiments. Those pollutants that weakly interact can be monitor using DE and “inverse” T2-filtered experiments. Finally, immobile contaminants in solid phases can be observed using CP/MAS and REDOR type experiments. We demonstrate that kinetics, molecular orientation of the contaminant, and the types of organic matter in soil (lignin, protein, cellulose, etc.) to which the contaminant binds can be determined using CMP-NMR.

RELAXOMETRY PROPERTIES OF WATER SATURATED LIGNIN CHARs

Conte Pellegrino^{*[1]}, Knicker Heike^[2], Berns Anne E.^[3]

^[1]Università degli Studi di Palermo ~ Dipartimento dei Sistemi Agro-Ambientali ~ Palermo ~ Italy ^[2]Instituto de Recursos Naturales y Agrobiología de Sevilla (IRNAS-CSIC) ~ Departamento: Geoecología, Biogeoquímica y Microbiología Ambiental ~ Sevilla ~ Spain ^[3]Forschungszentrum Jülich GmbH ~ Institute of Bio- and Geosciences IBG-3: Agrosphere ~ Jülich ~ Germany

Char is a very important organic system due to its role in affecting physical and chemical soil properties. In fact, it is reported that char has a positive effect on soil texture, pH, ionic exchange capacity and water retention. In the present study two chars were produced by heating lignin at 350°C for 30 and 240 s and were saturated with deionized water. Spin-spin relaxation time (T_2) measurements revealed that two different types of water molecules were present in both chars: a longer T_2 attributed to bulk water and a shorter T_2 assigned to bound water. Noteworthy, both T_2 values measured for the water in the 240 s char were longer than the respective T_2 values for the 30 s char sample. This discrepancy was attributed to the nature of the two different chars. In fact, the char obtained after 30 s heating still contained un-charred lignin molecules capable of strongly binding water molecules through formation of hydrogen bonds. Conversely, the char obtained after 240 s heating did not contain a lot of un-charred molecules, thereby favoring higher mobility degree of water molecules. NMR dispersion (NMRD) profiles confirmed the aforementioned findings through the evaluation of the correlation times. Relaxometry appeared a very suitable technique for the understanding of water dynamics in char samples. This is a very important issue since a prediction of water mobility in soils treated with different chars can be attempted.

In this work, we present our recent progress in mobile low-field NMR probe design for field measurements of natural soils: a slim-line logging tool, which can be rammed into the soil of interest on-site. The performance of the device is demonstrated in measurements of moisture profiles of model soils and field measurements of relaxometric properties and moisture profiles of natural soils. Furthermore, we present our recent results in 2D exchange relaxometry and simulation. These include relaxation-relaxation experiments on natural soils with varying degree of moisture saturation, where we could draw a connection between the relaxometric properties of the soil to its pore size-related diffusivity and to its clay content, and relaxation-relaxation experiments on flow through porous media. Also, models, simulations and possibilities are discussed to derive from the so obtained information a “characteristic pore shape” that can be used to characterize and to fingerprint natural soils.

The ability to predict future changes in soil organic carbon (SOC) stocks and potential additional sequestration lies in our understanding of the processes governing carbon storage over different periods of time. Scaling up to the molecular scale appears to be determinant to make progress on that issue as properties of functional groups rule interactions of SOC with soil phases and directly impact its turn-over. The emergence of new techniques combining isotope labelling with compound-specific isotopic analysis has recently provided a powerful means to quantify molecule fluxes and transformations over various time scales. Our intention was to implement this new knowledge on molecule cycling into numerical models for SOC dynamics. We present here C2SOM (Compound-Specific Simulation of Organic Matter dynamics), a model that represents in a simple way the dynamics of molecular constituents within total soil organic matter. C2SOM is derived from existing compartmental models of bulk soil carbon by inserting the compounds of interest inside each compartment and describing molecular fluxes and transformations between compartments. We present how C2SOM was calibrated to provide accurate description of the stocks and dynamics of lipid and carbohydrate moieties in soil and show applications. We also explore the model responses regarding critical questions such as the age of individual molecule in soil. We demonstrated that many individual lipids and carbohydrate molecules can be found in both young and old carbon pools. Finally we highlight some challenging issues arising from the development of such a molecular model.

The world experiences important land use changes which strongly affect the global carbon cycle and primarily one of its key compartments, the soil organic carbon (SOC). One way to understand the fundamental processes is to focus on SOC specific compounds, such as lipids, which are important SOC components influencing soil physical and chemical properties. The sylviculture located at the Republic of Congo, is a 30 years C4/C3 chronosequence, where native savanna (C4) was replaced with eucalyptus (C3). Molecular composition of the apolar lipids was determined in plants and soils, and 13C and 14C measurements were achieved for relevant plant markers: pentacyclic triterpene methyl ethers (PTMEs), specifics for the savanna vegetation, and odd long chain n-alkanes common to both vegetations. The PTMEs remained abundant in soils after 30 years of eucalyptus cropping and 13C analysis displayed constant d13C over the trial. Nevertheless, their 14C content increased along the chronosequence pointing to the mineralisation of more stabilized PTMEs. Compound-specific 13C analyses of soil n-alkanes showed typical trend of a C4/C3 vegetation shift, whereas 14C analysis displayed that the n-alkane pool comprised a significant amount of n-alkanes from a former C3 vegetation. 14C content also revealed high levels of mineralisation of the younger n-alkane pool within the first years of the trial. Afterwards, 14C content reflected the contribution of new n-alkanes from the eucalyptus vegetation. Therefore, combination of compound-specific 13C and 14C analyses revealed that afforestation caused dramatic changes in soil lipid composition, which will probably affect soil chemical and physical properties.

COUPLING POSITION-SPECIFIC LABELLING AND COMPOUND-SPECIFIC ¹³C-PLFA-ANALYSIS TO ASSESS MICROBIAL UTILIZATION OF AMINO ACIDS IN SOIL

Apostel Carolin^{*[1]}, Dippold Michaela^[2], Glaser Bruno^[3], Kuzyakov Yakov^[2]

^[1]University of Bayreuth ~ Dep. of Agroecology ~ Bayreuth ~ Germany ^[2]Georg-August-University of Göttingen ~ Department of Soil Science of Temperate Ecosystems ~ Göttingen ~ Germany ^[3]Martin-Luther-University of Halle ~ Soil Biogeochemistry, Institute of Agricultural and Nutritional Science ~ Halle ~ Germany

Microbial utilization of low molecular weight organic substances (LMWOS) is one of the key processes of their transformation in soil. Position-specific labeling combined with compound-specific ¹³C-PLFA-analysis is a unique tool for tracing of LMWOS transformation in soil. We assessed short-term (3 and 10 days) transformations of amino acids by adding position-specifically labeled ¹³C alanine and glutamic acid to soil in a field experiment. We quantified the microbial utilization of the functional groups by ¹³C analysis of microbial biomass by chloroform-fumigation-extraction. Furthermore, the utilization of individual C positions by distinct microbial groups was evaluated by ¹³C-PLFA approach. Microbial degradation was fastest with the highly oxidized carboxylic groups of both amino acids, whereas reduced C positions, e.g. C3 and C4, showed higher incorporation into microbial biomass and PLFA. The incorporation of C2 position differed significantly depending on amino acid, microbial group and time. Whereas C2 of alanine was still bound to C3 at day three, this fragment was already partially split at day ten. In contrast, the C2-group of glutamic acid was degraded much faster, which reflects the utilization of glutamic acid as general N donor. Thus, incorporation of C2 of glutamic acid into microorganisms can be used as marker for N metabolism of distinct microbial groups. Observing the fate of single C atoms by position-specific labeling allows conclusions about the mechanisms and kinetics of microbial utilization and interaction between these groups and therefore will improve our understanding of soil C fluxes.

S07.03a -4

CAN WE TRACE CHANGES IN ORGANIC MATTER QUALITY BY MULTI-ISOTOPE LABELLING (13C, 18O AND 2H)?

Studer Mirjam S.*^[3], Samuel Abiven^[3], Rolf T. W. Siegwolf^[2], Michael W. I. Schmidt^[3]

^[1]University of Zurich ~ Geography, Soil Science and Biogeography ~ Zurich ~ Switzerland ^[2]Paul Scherrer Institute ~ Laboratory for Atmospheric Chemistry ~ Villigen ~ Switzerland ^[3]University of Zurich ~ Department of Geography, Soil Science and Biogeography ~ Zurich ~ Switzerland

The dynamics of organic matter (OM) cycling within the plant soil-system are determined by environmental parameters, as well as chemical quality of OM input. A well-known technique to study OM dynamics is to label OM inputs with stable isotopes (e.g. 13C). Changes in OM quality in the plant and in the soil can be assessed by compound specific isotopic analysis. These techniques give a precise insight of the OM composition, but are laborious and expensive. Here we suggest a new multi-isotope labelling technique using stable 13C, 18O and 2H isotopes, which provides information on OM quality by simple bulk material analysis. The method is based on the creation of an isotopic van Krevelen diagram, which is used to describe different compound groups by plotting the atomic ratios of O/C vs. H/C. We could show that new assimilates can be labelled with 13C, 18O and 2H by adding the stable isotopes (continuously) in the gaseous phase (CO2 and water vapour). The label has been traced within the bulk material of different compartments of the plant-soil system. Our first results showed that after 2, 8 and 14 days of labelling the 18O/13C(new) ratio was significantly different in leaf, stem and root tissue (0.0024, 0.0011 and 0.0007, respectively), suggesting a change in OM quality towards more C-rich compounds (e.g. sugars -> lignin). d2H analysis will follow and an isotopic van Krevelen diagram will be produced (18O/13C(new) vs. 2H/13C(new)) to describe the changes in OM quality.

The most significant effect that microbial communities have on their environment is their ability to recycle the essential elements. Amino sugars (ASs) are specific compounds of microbial cell wall and have widely been used to investigate the soil microbial communities and organic residue's sequestration processes. However, little is known about the dynamics of AS in soil. We conducted an incubation experiment with ¹³C-labeled wheat residues on topsoil of conventional till and no-till soil, with three different residue qualities. The isotopic composition of the AS was measured using LC-c-IRMS. Results showed that the unlabeled pool (ASSOM) was relatively stable, while the "de novo" formed ASs could be assumed to be almost entirely crop residue derived (ASR). Dynamic AS accumulation obeys the first-order kinetics $AS_t = AS_{Max} \cdot (1 - e^{-kt})$, and reaches a maximum within several days (GlcN and GalN) or even hours (MurN). Dynamic AS formation rates and maxima strongly depend on the available substrate quality, as well as by original microbial community structure due to different tillage condition in situ. High quality of grain significantly promotes the dynamic AS formation rates as well as its final concentration. However the carbon use efficiency, defined here as the amount of C mineralized to produce AS, was inversely proportional with the residue quality as root was highest and grain lowest. The responses of microbial consortia under conventional tillage to the added organic residues were faster than those in no-till; however, the total de novo AS production was higher in no-till.

^[1]University Koblenz-Landau, Institute for Environmental Sciences ~ Environmental and Soil Chemistry ~ Landau ~ Germany

Nanothermal analysis (nTA) coupled with Atomic force microscopy (AFM) of soil samples has potential to improve our understanding of physicochemical processes in soil and to link nanospatial and microspatial distribution of thermal characteristics with macroscopic properties of soil samples. We compared macroscale characteristics (DSC, TGA-MS) and nanoscale thermal characteristics (AFM-nTA) of natural and artificial soils treated with different organic material and fertilizers. The soil samples revealed different types of macroscopic and nanoscale characteristics and heterogeneity. Thermogram types consisted of partly structured expansion and compression phases suggesting material-specific thermal profiles. The distribution of thermogram types reflected sample-dependent nanoscale and microscale heterogeneity. We found indications for water molecule bridge (WaMB) transitions by nTA in peat and soil samples. Organic materials generally revealed strong expansion and irreversible compression phases, latter probably due to collapse of pore and aggregate structures. All investigated samples are heterogeneous on the nanoscale and microscale with respect to thermal behaviour. AFM-nTA allows distinguishing numerous different materials on nanometer and micrometer scale in soil samples. The material-dependent characteristics will help to understand and learn more about the nanoscale distribution of different materials and properties as well as biogeochemical processes. Related to the macroscopic thermal behavior, this will allow studying links between properties of biogeochemical interfaces and processes governed by them.

Most knowledge on lignin decomposition is based on wood and aerobic systems. In anaerobic systems such as peatlands, decomposition may be different. In addition to mosses, peat is built-up of both woody and herbaceous vascular plant remains, which may show different decay patterns. Lignin parameters that are generally applied to indicate the state of decay of organic matter include the abundance of lignin, ratios of different lignin moieties, and both oxygenation and chain length of lignin alkyl side-chains. The parameters are usually obtained by the CuO oxidation method. The same parameters, obtained with pyrolysis-GC/MS, are applied to a high-resolution sampled peat core. The lignin composition of dominant plant species (graminoids and ericoids) and different peat fractions (NaOH-extractable, bulk, and non-extractable residues) were also studied with pyrolysis-GC/MS. Several decomposition stages were recognized that differently affected lignin decay. These are: 1) early stage of plant decay, 2) long term anaerobic decomposition, and 3) aerobic decomposition during subsequent periods of drought. Our results indicate preferential decay of guaiacyl over syringyl moieties during the first stage of decay. This can be explained by the fact that large part of the guaiacyl moieties are not part of the lignin polymer. Anaerobic conditions during the first stage caused oxygenation of C3 alkyl side-chains; for syringyl lignin this effect was stronger than preservation. Our results show that lignin decay highly depends on composition of the source material, and suggest that lignin decomposition parameters that are commonly used in aerobic environments, may lead to erroneous interpretations in wet environments.

SOLUBLE PHENOLS REFLECT THE DECOMPOSITION OF LEAF AND NEEDLE LITTER

Klotzbücher Thimo^{*[5]}, Kaiser Klaus^[5], Filley Timothy^[4], Kalbitz Karsten^[3]

^[1]Martin-Luther-University of Halle-Wittenberg ~ Soil Science ~ Halle ~ Germany ^[2]Purdue University ~ Earth and Atmospheric Sciences ~ West Lafayette ~ United States ^[3]University of Amsterdam ~ Institute for Biodiversity and Ecosystem Dynamics ~ Amsterdam ~ Netherlands ^[4]Purdue University ~ Earth and Atmospheric Sciences ~ West Lafayette ~ United States ^[5]Martin-Luther-University of Halle-Wittenberg ~ Soil Sciences ~ Halle ~ Germany

Microbial breakdown of polyphenolic macromolecules such as lignin and tannin yields water-soluble compounds that greatly contribute to organic matter dissolved in the percolation water of soils. The compounds, mainly acidic, determine environmentally relevant reactions of dissolved organic matter such as metal complexation, sorption to mineral surfaces, and protein precipitation. We hypothesised that production of water-soluble phenolic compounds over time is directly linked to the course of litter decomposition, with hydrolysable tannins being the major sources in the beginning and lignin at later stages. An experiment was carried out, in which five types of litter (ash, beech, maple, pine, spruce) were exposed to degradation in the field for 27 months. Soluble compounds produced during decomposition were extracted into water. Litter samples as well as dried-down water extracts were analysed for lignin- and tannin-derived phenols using ¹³C-labelled tetramethylammonium hydroxide thermochemolysis. All litter samples varied more strongly in their contents of tannin than of lignin. Production of soluble tannin was largest at the initial stages of litter decomposition and diminished with time. Lignin degradation was also strongest at initial degradation stages and decreased strongly with time, presumably due to decreasing availability of easily degradable compounds. Water-soluble phenols closely reflected those changes, with large releases of both tannin- and lignin-derived phenols at early stages of decomposition. Later, the contribution of tannin-derived phenols to water soluble fractions diminished and lignin-derived phenols became more prevalent. The study again showed that dissolved organic compounds are excellent indicators of soil processes.

LINKING SOIL ORGANIC MATTER DYNAMICS AND DISSOLVED ORGANIC MATTER IN SOIL DEPTH PROFILES

Gleixner Gerd^{*[1]}, Andrea Scheibe^[1], Ashish Malik^[1]

^[1]Max Planck Institute for Biogeochemistry ~ Biogeochemical processes ~ Jena ~ Germany

The role of dissolved organic matter (DOM) for carbon flow in soils is still not well understood. We used natural labelling of plants to trace the flow of carbon into soil organic matter (SOM) and DOM size classes in order to understand the link between plants, SOM and DOM. Two experimental plots with different soils types were cultivated each with C3 and C4 plants for several years. The annual litter input was held identical for all plots avoiding input related changes in the carbon turnover. SOM, DOC and soil gases were collected at 10, 20 and 30 cm depth and their ¹³C signal was determined using isotope ratio mass spectrometry (IRMS). DOM was fractionated by size exclusion chromatography and their compound specific isotope ratios were measured on line. Our results demonstrate that the contribution of plant-derived carbon into DOM varies with parent material, depth and size classes. Plant signals are mainly found in the winter, in larger DOM fractions and in upper soil horizons. Soil-derived carbon is mainly found in smaller fractions, in the summer and in deeper soil horizons. This suggests that soil microorganisms decompose plant-derived carbon input and that this is inducing the export of smaller soil-derived DOM.

MOBILITY AND STABILITY OF ROOT AND NEEDLE SPECIFIC BIOMARKERS IN A LONG-TERM INCUBATION STUDY WITH CONTINUOUS LEACHING

Altmann Jens G.*^[1], Jansen Boris^[1], Nierop Klaas G.j.^[2], Kalbitz Karsten^[1]

^[1]University of Amsterdam ~ Institute for Biodiversity and Ecosystem Dynamics ~ Amsterdam ~ Netherlands ^[2]Utrecht University ~ Department of Earth Sciences – Geochemistry ~ Utrecht ~ Netherlands

Up to now there is only a poor understanding of the sources contributing to organic carbon in forest soils, especially the relative contribution of leaves versus roots. Compounds being specific for leaves and roots might be a promising tool to improve our knowledge of different sources of soil organic matter (SOM). Surprisingly, information about the dynamics of root- and leaf-derived biomarkers during litter decomposition is scarce. For quantitative application of the biomarker approach not only the stability of these specific molecules has to be considered, but also their mobility within the soil profile has to be determined. This information is necessary, if we want to assess the dynamics of biomarkers in soils and to use them for source identification and quantification. We analyzed the changes in chemical composition of roots and leaves and their water-extractable fraction of six temperate tree species during a 6-months incubation experiment in the laboratory. In this study we focused on the following questions: (I) How stable are species-, leaf- and root-specific molecules (e.g., lignin, cutin, suberin) during litter decomposition? (II) How mobile are these polymer-derived molecules during leaching experiments? During this long-term experiment we measured continuously carbon and nitrogen contents of the water extracts and the remaining residues, C mineralization rates, and the chemical composition of water extracts and residues by e.g., Curie-point pyrolysis mass spectrometry and thermally assisted hydrolysis and methylation.

CHANGES IN PLANT BIODIVERSITY, SOM CONTENT AND COMPOSITION IN A LONG TERM DRAINAGE EXPERIMENT

Wolf Katharina^{*[1]}, Roland Bol^[2], Jennifer Dungait^[2], Jennifer Dungait^[2], Elisabeth Dixon^[2], Dan Dhanoa^[2], Deborah Beaumont^[2], Guido Wiesenberger^[1]

^[1]University of Bayreuth ~ Agroecosystem Research Department ~ Bayreuth ~ Germany ^[2]Rothamsted Research, North Wyke ~ North Wyke Research ~ Okehampton ~ United Kingdom

Moisture and slope position can have a strong influence on soil properties and plant communities. In a long term permanent grassland experiment, sub-surface drainage was introduced in 1982 on some plots of Rowden Moor at North Wyke (SW UK). The soil is a Stagnic vertic Cambisol with a dense clay layer at shallow depth. After drainage the plant community had shifted from a Lolium perenne dominated grassland with patches of Juncus sp. towards a typical grassland plant community dominated by Lolium perenne and Trifolium sp. In addition, soil carbon and nitrogen concentrations tended to decrease. This is related to a smaller contribution of plant-derived organic matter due to the change in plant community structure, and the enhanced mineralization of SOM under lower soil moisture. Furthermore the $\delta^{13}\text{C}$ values tend to get more negative in soil, which could be related to the changing plant community. Changes in the chemical composition of soil organic matter (SOM) were examined using compositional changes of soil n-alkanes. A shift in the alkane abundance occurs from the upper part of the slope (dominated by n-C31), to the bottom parts (n-C29 enriched). The carbon preference index and average chain length of alkanes correlated between undrained and drained plots and decreased down slope. Similarly, several alkane ratios like n-C27/n-C31 declined, due to the enhanced mineralization. The study showed that drainage has a long term effect on the plant community leading to depletion in C- and N- contents and a change in the chemical composition of SOM.

Investigating organo-mineral associations in topsoil and subsoil horizons may help understanding soil organic matter (SOM) stability in these horizons and their potential to retain C and N from recently added organic matter. We used a sequential density fractionation procedure coupled with X-ray diffraction (XRD) analysis to investigate the retention of autochthonous and residue-derived C and N in topsoil (0-20 cm depth) and subsoil (30-70 cm depth) samples coming from the profile of a weakly weathered heavy clay soil incubated without (0 g C kg⁻¹) or with (10 g C kg⁻¹) ¹³C-¹⁵N-labelled residues for 51 d. A greater proportion of soil organic carbon (SOC) and N was associated with soil mineral phases in subsoil than topsoil. Similar amounts of residue-derived C and N were retained in both soils, but greater amounts were found in organo-mineral complexes of subsoil than topsoil. In both autochthonous and residue-derived organo-mineral associations, our results are consistent with a theoretical model that predicts preferential sorption of N-derived compounds on unsaturated mineral surfaces. We conclude that these N-derived compounds have key role as binding agents during the formation of organo-mineral complexes in a weakly weathered heavy clay soil.

Our aims were to determine how an *in situ* simulated short term (2009 to 2011) warming affects the properties of sensitive OM, i.e. water-extractable organic matter (WEOM) in a Sphagnum peatland (Le Forbonnet, France). This was performed through the analyses of the WEOM extracted from 4 to 6 levels of surface peat. Peat was sampled in two contrasted sites: an open bog and a transitional poor fen. Open-Top Chambers (OTCs) which were used for warming experiment led to a significantly increase of mean air temperature of ca. 1.3°C in spring and summer. OTCs did not impact vegetation communities. Therefore, WEOM changes had been assigned (i) to microbial activities at peat surface and (ii) to microbial activities and/or roots exudates with depth. After three years of warming, no effect on WEOM properties were found at the bog site even if β -glucosidase indicated that OTCs induced a lower decomposition. However, at the fen site OTCs impacted the WEOM properties following two patterns: - a lower carbon and sugars contents at the peat surface suggesting a greater microbial decomposition as shown by β -glucosidase activities. - a greater carbon and sugars contents with depth (ca. 10 cm) suggesting a lower decomposition dynamic induced by OTCs treatment. OTCs effects on WEOM properties present a strong variability following depth but also micro-environmental conditions. Therefore, it appears that 3D spatial variability is a critical key element to understand OM dynamics and carbon fate in peatlands.

THE INFLUENCE OF PRECIPITATION AND TEMPERATURE ON SOIL ORGANIC MATTER DYNAMICS IN A DUTCH MIXED FARM SYSTEM

Lantinga Egbert^[1], Hoogsteen Martine^{*[1]}

^[1]Wageningen University and Research centre ~ Organic Farming Systems ~ Wageningen ~ Netherlands

Soil organic matter (SOM) decline is identified as a major threat for agricultural soils worldwide. Furthermore, the concern about negative effects of climate change on SOM dynamics has grown. This study investigates the relation between precipitation and temperature on yearly changes in SOM for a 123 ha mixed farm in the Netherlands on a clayey soil. The crop rotation included arable food and feed crops, vegetables and grass-clover leys. The livestock component consisted of dairy cows with their young stock and sheep. The leys were predominantly grazed, and indoors both slurry and farmyard manure were produced. The cattle diet was characterised by low protein and high fiber contents. During a period of 7 successive years, a complete crop rotation cycle, the 0-30 cm layer in all of the 66 parcels was sampled each early spring period. Average yearly changes in soil organic carbon (SOC) were determined at farm level (Kurmies method) by taking into account the area variation between the individual parcels. Linear regression analyses were carried out for relating yearly differences in SOC with the preceding 365-days precipitation and average temperature. A strong decreasing correlation was found for delta SOC and precipitation ($R^2 = 0.80$) with negative values above 968 mm. However, only a weak negative correlation could be detected between delta SOC and temperature ($R^2 = 0.29$).

^[1]Bioforsk ~ Jord og miljø ~ AS ~ Norway ^[2]Norwegian University of Life Sciences (UMB) ~ Plant and Environmental Sciences ~ Ås ~ Norway ^[3]Bioemco ~ Soil ~ Thiverval-Grignon ~ France ^[4]Università degli studi di Firenze ~ Scienza del suolo e nutrizione della pianta ~ Firenze ~ Italy

Soil organic matter (SOM) in arctic permafrost-affected soils is the largest terrestrial reservoir of carbon (C). With the expected climate warming, increased SOM decomposition in these soils is considered as the largest potential positive feedback from terrestrial ecosystems to the atmosphere. The chemical composition of SOM in permafrost-affected soils is not well documented, although it might be a main driver for the response of the huge C stocks in permafrost-affected soils to increasing temperatures. Here, our objective was to verify whether it was possible to relate the temperature response of SOM mineralisation to SOM molecular composition in eight contrasted permafrost-affected soils of Norway, Svalbard and Russia sampled at two different depths. To this end, precise parameterisation of the temporal response of arctic soils to increased temperatures was estimated with a two pool first-order kinetics model while molecular data concerning composition and state of decomposition of SOM were acquired. Results showed that SOM dynamics was first controlled by soil type (i.e. organic vs. mineral soils) and then by the depth and frost status, with no influence of the site, whereas SOM quality was mostly site and soil type dependent. No simple relationships could be derived between molecular data and SOM dynamics parameters, suggesting that factors other than SOM quality would be the main controllers of SOM dynamics in the studied permafrost-affected soils.

S07.04 -4

SOC DYNAMICS IN GRASSLANDS: PLANT-MEDIATED EFFECTS, DRIVING FACTORS AND MICROBIAL RESPONSE

Schulz Elke^{*[1]}, Marc Breulmann^[1], Karoline Weißhuhn^[1], Francois Buscot^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Soil Ecology ~ Halle ~ Germany

The likely effects of climate change on vegetation composition and ecosystem processes have been widely studied. However, few studies have explored associated plant-mediated effects on biogeochemical processes, such as SOM dynamics and its availability to decomposers. We describe effects of plant litter on SOC and on soil microbial activity and structure in extensively managed grasslands in Central Germany to identify biotic and abiotic factors driving the SOC dynamics. The decomposition of shoot and root litter was studied in an incubation experiment. Labile C and N were isolated by hot water extraction; functional groups of microbes were identified by PLFA analysis and microbial activity was measured using a set of soil exo-enzymes. Plant community composition, particularly legume species affected SOC dynamics and microbial processes, especially via roots, reflected in different decomposition course of root litter. The labile SOC pool was found to be a key driver of the below-ground food web, controlling soil microbial processes. Below-ground responses appear to be related to the presence of legume species, which affected microbial communities, the ratio between fungal and bacterial biomass and patterns of soil enzyme activity. Low productivity fungal-dominated grasslands with slow C turnover may play an important role in SOC accumulation. The examined interrelationships between abiotic and biotic factors are important for predicting decomposition rates in soils and the loss of SOC, and thus of both present ecosystem functions and changes that may occur following anticipated climate change.

S07.04 -5

LONG-TERM FERTILIZATION AND SOIL WARMING EFFECTS ON RECALCITRANT LITTER DECOMPOSITION

Dingemans Bas^[1], Hefting Mariet^[1], Verhoeven Jos^[1]

^[1]Utrecht University ~ Ecology & Biodiversity ~ Utrecht ~ Netherlands

The decomposition of soil organic matter (SOM) can be controlled by temperature and nitrogen enrichment; the former is generally considered to be an important stimulating factor of decomposition rates, while the influence of nitrogen enrichment is strongly dependent on the phase of decomposition and the chemical structure of the substrate. The chemical structure (e.g. distribution of C compounds) of SOM is an important factor that influences SOM decomposition. The formation of SOM is essentially controlled by the quantity and quality of plant litter inputs. Temperature change and increased nitrogen deposition may affect the chemical composition of plant litter and, in turn, affect the decomposition. This study investigated how increased nitrogen deposition in addition to global warming will affect the carbon turnover in wet grassland soils and, particularly, the decomposition of recalcitrant carbon compounds. We performed a long-term lab incubation experiment with litter from fertilized geothermally heated grassland plots in order to compare temperature and fertilization effects on decomposition. We found that nitrogen fertilization mitigated the accelerating effect of increased temperature on the decomposition of recalcitrant litter in grasslands. A lower quality (i.e. higher C:N ratio) of fertilized litter may have caused this mitigating effect. However, a lower lignin content of the fertilized litter did not seem to stimulate the decomposition. This may suggest a litter quality shift due to a shift in plant species composition, introducing other types of recalcitrant compounds, rather than a shift in carbon fractions within one species.

SOIL AND PLANT CARBON LOSS ASSESSMENT AFTER LAND USE CHANGE ON STEEP SLOPES IN NORTHWESTERN VIETNAM

Häring Volker^[1], Fischer Holger^[1], Stahr Karl^[1]

^[1]University of Hohenheim ~ Institute for soil science and land evaluation ~ Stuttgart ~ Germany

*Continuous cultivation of maize is commonly practiced on steep slopes in northwestern Vietnam. Carbon losses associated with land use change from forest to maize have an impact on soil degradation and climate change. The aim of our study was to assess the carbon dynamics on three soil types. We determined soil organic carbon (SOC) loss rates by (1) soil erosion and (2) decomposition of forest-derived SOC, (3) maize derived carbon input as well as carbon storage of (4) forest and (5) maize plants. On three soil types chronosequences of up to 21 years of continuous maize cultivation after deforestation were established. Stable carbon isotopes, total organic carbon and bulk density were determined until 30 cm depth. Soil erosion was measured with ¹³⁷Cs. Plant biomass was estimated based on diameter and height of plants as well as litter fall measurements. Slash and burn of the primary forest caused emissions of 78 t CO₂ ha⁻¹. Burning of maize harvest residues caused emissions of 2.4 t CO₂ ha⁻¹a⁻¹. Decomposition of SOC caused CO₂ emissions of 1.1 t*ha⁻¹*a⁻¹. Soil erosion relocated 0.8 t C ha⁻¹*a⁻¹. The maize root biomass C which entered the SOC pool was calculated as 2.0 t*ha⁻¹*a⁻¹. The rate of maize derived SOC was 0.2 t*ha⁻¹*a⁻¹. Summarized the system was subject to a high initial C loss by deforestation followed by a net C loss of 6.1 t*ha⁻¹*a⁻¹. These results demonstrate the negative C balance since land use change and highlight the contribution of current management practices to climate change.*

THE FORGOTTEN PART OF CARBON CYCLING: ORGANIC MATTER STORAGE AND TURNOVER IN SUBSOILS

Marschner Bernd*^[1]

^[1]Ruhr-University Bochum ~ Soil Science/Soil Ecology ~ Bochum ~ Germany

In the past, carbon flux measurements and modelling have mostly considered the topsoil where C-concentrations, root densities and microbial activities are generally highest. However, depending on climate zone and land use, this soil compartment contains only 30-50% of the C-stocks of the first meter. If the deeper subsoil down to 3 m is also considered, the contribution of topsoil carbon stocks to total soil C-pools is only 20-40%. Another distinct property of subsoil organic matter is its high apparent ^{14}C age. The ^{14}C age of bulk soil organic matter below 30 cm depth generally increases continuously indicating mean residence times of several 10^3 to 10^4 years. Large pool size and high radiocarbon age suggest that subsoil OM has accumulated at very low rates over very long time periods and therefore appears to be very stable. Several explanations have been proposed why subsoil SOM is so seemingly old and inert: 1. Subsoil SOM largely consists of recalcitrant compounds. 2. The annual inputs of fresh OM into the subsoil are extremely low. 3.

Old SOM in subsoils is stabilized by sorption to pedogenic minerals. 4. The high radiocarbon age is caused by fossil or geogenic C. 5. Microbial activities are limited by low O_2 and low temperatures. 6. Microbial activities are limited to very few hot spots In this review, the current state of knowledge regarding these hypotheses is presented and discussed to derive open questions and research needs for the near future.

^[1]Associate University of Leuven ~ Earth and Environmental Sciences ~ Leuven ~ Belgium ^[2]Research Institute for Nature and Forest ~ Geraardsbergen ~ Geraardsbergen ~ Belgium ^[3]Wageningen University ~ Earth System Science ~ Wageningen ~ Netherlands ^[4]Associated University of Leuven ~ Earth and Environmental Sciences ~ Leuven ~ Belgium

Between 30 and 63% of the soil organic matter (SOM) is stored below 30 cm, making subsoil SOM an important source and sink in the global carbon cycle. Nevertheless, detailed information regarding the composition of subsoil SOM remains scarce. This study aims to evaluate the extractable fraction of topsoil and subsoil horizons in broadleaved temperate marine forests from Flanders (Belgium) by analytical pyrolysis-gas chromatography/mass spectrometry. Six sites were chosen under Beech, Oak and hybrid poplar. All sites show a significant shift in chemical composition of the NaOH-extractable fraction between the topsoil and the subsoil. While the extractable SOM of the topsoil mainly differs in the accumulation of recalcitrants according to input and nutrient status, subsoil-SOM shows high relative amounts of aliphatics or polysaccharides for coarse and fine textured soils respectively. Lignins, lignin-derived phenols or aromatics are not major contributors to subsoil-SOM, regardless of soil type. Furthermore, results show that labile plant-derived molecules are present in the subsoil, i.e. long-chain aliphatics and cellulose-derived polysaccharides, which are neither inherently chemically recalcitrant nor highly humified.

THE EFFECT OF AGRICULTURAL LAND USE ON THE NATURE AND DYNAMICS OF SUBSOIL CARBON

Gregory Andrew^{*[1]}, Dungait Jennifer^[2], Dixon Elizabeth^[2], Bol Roland^[2], Whitmore Andrew^[1]

^[1]Rothamsted Research ~ Department of Sustainable Soils and Grassland Systems ~ Harpenden, Hertfordshire ~ United Kingdom ^[2]Rothamsted Research ~ Department of Sustainable Soils and Grassland Systems ~ North Wyke, Okehampton, Devon ~ United Kingdom

The significant effect of management on carbon (C) stocks in agricultural topsoils is widely reported but the effect on subsoil C is rarely considered. Conditions in the subsoil are considered to be more stable compared to the topsoil and hence the potential for C sequestration at depth has recently been highlighted. We analysed soils from some of the long-term field experiments at Rothamsted Research (UK) to investigate the nature and dynamics of subsoil C under different agricultural land uses over a range of timescales. Conversion of a grassland soil to arable uses resulted in a decrease in C contents down to 75 cm depth over a period of 60 years. In addition bulk ¹³C values were greater and plant biomarker n-alkane concentrations were lower under arable management compared to grassland, indicating a change in the composition of subsoil C. In contrast, an arable soil reverted to grassland or woodland had increased considerably its C content down to at least 70 cm depth over the intervening 130 years with a coincident reduction in the mean ¹⁴C age of subsoil C following conversion, indicating significant novel C input at depth. We have demonstrated the significant influence of agricultural management on the nature and dynamics of subsoil C, with sequestration under grassland and losses under arable management. Analysis of plant biomarkers suggests that roots provide a direct input of fresh C to the subsoil. We conclude that agricultural management significantly affects subsoil C stocks through its influence on biotic and abiotic drivers.

S07.05 -4

CYCLING DOWNWARDS – DISSOLVED ORGANIC MATTER IN SOILS

Kalbitz Karsten^{*[1]}, Kaiser Klaus^[2]

^[1]University of Amsterdam ~ Earth Surface Science, Institute for Biodiversity and Ecosystem Dynamics ~ Amsterdam ~ Netherlands ^[2]Martin Luther University Halle-Wittenberg ~ Soil Sciences ~ Halle ~ Germany

Dissolved organic matter has been recognised as mobile, thus, crucial to translocation of metals, pollutants, and nutrients in soil. We present a conceptual model of the vertical movement of dissolved organic matter with soil water, which deviates from the common view of a chromatographic stripping along the flow path. It assumes temporal immobilisation (sorptive or by co-precipitation), followed by microbial processing, and re-release (by desorption or dissolution) into soil water of altered compounds. The proposed scheme explains well depth trends in age and composition of dissolved organic matter. Our conceptual model also offers an immediate explanation of the increase in radiocarbon age and the compositional change of solid-phase (mineral-associated) organic matter with depth observed in many soils. Dissolved organic matter is probably not only indicative for transformation and transport processes but is representative for the cycling of soil organic matter in general.

S07.05 -5

SOIL CARBON STABILIZATION IS DRIVEN BY THE RATIO OF C INPUT TO THE MASS OF MINERAL SOIL

Leifeld Jens*^[1], Franz Conen^[2]

^[1]Agroscope Reckenholz-Tänikon ART ~ Air Pollution / Climate Group ~ Zurich ~ Switzerland ^[2]Universität Basel ~ Environmental Geosciences ~ Basel ~ Switzerland

Soil carbon mean residence times (MRT) increase with soil depth although combined temperature and moisture effects on organic matter (OM) decomposition may be favorable in deeper soil. Smaller OM/mineral ratios in subsoils foster organo-mineral stabilization. Additionally, the highly diluted substrate makes it less attractive for organisms to produce exoenzymes. In consequence, one would expect MRT to be a function of the amount of carbon input per unit mineral soil. This effect should be more pronounced for mineral-associated (MOM) than for particulate (POM) OM because turnover of the latter is also driven by factors such as POM quality. Carbon input and MRT of MOM and POM was calculated for various well-drained upland soils and soil layers ($n=55$) using the radiocarbon approach. 84% of MOM MRT variability is explained by the ratio of carbon input to mineral soil mass. The relationship improves to 95% when calculated per mass of clay. The mechanism becomes relevant at annual C inputs of 0.2 g C kg⁻¹ soil. Below this rate, stabilization by the mineral matrix overrides other environmental controls. Correlation between POM input per soil mass and its turnover rate is weaker but still highly significant. While soil pH and temperature are important factors for carbon turnover in the studied soils, OM MRT can be expressed as a function of C input rate per unit soil mass because it seems mainly driven by the OM stabilizing capacity and OM dilution of/in subsoil. Consequently, low-productive ecosystems should promote long soil carbon MRT.

ARE DECOMPOSITION AND STABILISATION PROCESSES OF ORGANIC MATTER IN SUBSOILS RELATED TO REDUCED MICROBIAL BIOMASS AND ACTIVITY ?

Rumpel Cornelia^[1], Sanaullah Muhammad^[2], Baumann Karen^[1], Marron Pierre Alain^[6], Chabbi Abad^[4]

^[1]CNRS ~ BIOEMCO ~ Thiverval-Grignon ~ France ^[2]University of Agriculture ~ Institute of Soil and Environmental Sciences ~ Faisalabad ~ Pakistan ^[3]University of Agriculture ~ Institute of Soil and Environmental Sciences ~ Faisalabad ~ Pakistan ^[4]INRA ~ UR Ecophysiologie des plantes fouragères ~ Lusignan ~ France ^[5]INRA ~ UR Ecophysiologie des plantes fouragères ~ Lusignan ~ France ^[6]INRA ~ Microbiology ~ Dijon ~ France

Stabilisation of organic matter (OM) in subsoils results in higher residence times compared to topsoil OM and may thus have different controls. In particular, contrasting stabilisation mechanisms, energy limitations as well as reduced number and diversity of the microbial biomass in subsoils were hypothesised to be responsible for OM accumulation. The OM input into subsoil may be root derived. A field incubation experiment with ¹³C and ¹⁵N labelled root litter in three different soil depths during 36 months showed similar decomposition but higher plant litter alteration in subsoil as compared to topsoil. Decomposition dynamics in subsoil horizons showed a lag phase. Protection of OM occurred in soil aggregates as well as by adsorption to soil minerals. These two stabilisation mechanisms were found to be equally important in top- and subsoil horizons. After three years of incubation, the amount carbon remaining was similar in top- and subsoil horizons despite contrasting microbial biomass, potential enzyme activity and microbial community structure. Loss of soil inherent ancient OM due to priming was not detectable. In our incubation experiment, abiotic conditions were found to be only slightly different in top- and subsoil horizons. The organisation of the soil profile and in particular the heterogeneity of fresh litter input may be the most important parameter determining subsoil OM dynamics. All processes, which alter the horizontal organisation of soil, such as plant rooting and preferential flow pathways might influence controls on OM stabilisation in subsoils.

Precise estimations of soil organic carbon (SOC) stocks are of decided importance for the detection of C sequestration or emission potential induced by land use changes. For Germany, a comprehensive, land use-specific SOC data set has not yet been compiled. We evaluated a unique data set of 1460 soil profiles in southeast Germany in order to calculate representative SOC stocks to a depth of 1 m for the main land use types. The results showed that grassland soils stored the highest amount of SOC whereas considerably lower stocks were found for forest and cropland soils. However, the differences between extensively used land (grassland, forest) and cropland were much lower compared with results from other studies in central European countries. The depth distribution of SOC showed that despite low SOC concentrations in A horizons of cropland soils, their stocks were not considerably lower compared with other land uses. This was due to a deepening of the topsoil compared with grassland soils. Higher grassland SOC stocks were caused by an accumulation of SOC in the B horizon which was attributable to a high proportion of C-rich Gleysols within grassland soils. This demonstrates the relevance of pedogenetic SOC inventories instead of solely land use-based approaches. Our study indicated that cultivation-induced SOC depletion was probably often overestimated since most studies use fixed depth increments. We recommend SOC stocks be determined by horizon for the entire soil profile in order to evaluate C sequestration potentials more accurately.

THE VARYING CONTRIBUTION OF PEDOGENE OXIDES AND CLAY MINERALS TO STABILIZE CARBON ALONG A SLOPE TRANSECT

Doetterl Sebastian^{*[1]}, Jean-Thomas Cornelis^[2], Johan Six^[3], Kristof Van Oost^[1]

^[1]University of Louvain ~ TECLIM ~ Louvain-la-Neuve ~ Belgium ^[2]University of Louvain ~ ELIE ~ Louvain-la-Neuve ~ Belgium ^[3]University of California at Davis ~ Department of Plant Sciences ~ Davis ~ United States

Research in the Belgian Loambelt has shown that the quality and quantity of soil organic carbon (SOC) in sloping cropland differs with topographic position, despite similar soil substrate and drainage conditions. These differences were most visible in the subsoil, while the size and composition of topsoil C pools were similar along the hillslope. Relative to stable or eroding sites, three to nine times as much C is stored in the subsoil (up to 1m depth) of depositional sites. This is related to the burial of former topsoil and high amount of carbon there is stabilized mainly as microaggregate and silt associated C fractions. We assume that the presence of different forms of pedogene Oxides (PO) and varying clay mineralogy are crucial for these differences along the hillslope. Here, we present an analysis that aims to clarify the chemical and mineralogical components involved in stabilizing carbon at various depths and slope positions. The results show that forms of POs associated with different C pools differ clearly along the slope transect. At eroding sites, more POs are associated in metal-organic complexes, while at depositional sites more amorphous and poly-crystalline minerals can be found. These minerals have varying abundances within the different C fractions, with more amorphous and poly-crystalline POs associated with stable aggregates. In combination with a changing clay mineralogy based on the available substrate for soil formation, we conclude that these units are key for the understanding of the fate of eroded and buried carbon on the hillslope scale.

S07.06a -3

THE EFFECTS OF LAND CONVERSION TO BIOENERGY CROPS ON SOIL CARBON

Mcclean Gary*^[1]

^[1]University of Edinburgh ~ School of Geosciences ~ Edinburgh ~ United Kingdom

*As global demand for renewable energy increases to assist in reducing greenhouse gas (GHG) emissions, the projected future expansion in bioenergy production is expected to cause significant land-use change. The main aim of this project is to provide an improved understanding of changes in soil organic carbon (SOC) when land is converted from arable crops or grassland to willow short rotation coppice (SRC) or *Miscanthus x giganteus* bioenergy cropping systems. Studies indicate that, in addition to providing combustible material to substitute fossil fuels, these bioenergy crops may provide an additional benefit through SOC accumulation. However, other studies have found a loss in SOC following land-use change and the variation in results demonstrates the sensitivity of SOC to a range of factors such as climate, soil texture, previous land-use and SOC content. In this project soil samples have been taken from a chrono-sequence of 100 sites from across England, Scotland and Wales that are currently in transition to willow SRC or *Miscanthus* bioenergy plantations. Soil analysis for SOC content will help to determine the effects of 'time since change' for each land replacement scenario and to indicate the magnitude of any initial loss of soil C, the period of recovery and the new soil C equilibrium reached. The data collected in this study will help to quantify how land conversion from arable crops or grassland to *Miscanthus* or willow SRC will affect soil C stocks and enable identification of optimal land for conversion to bioenergy cropping systems.*

COMPOSITION AND TURNOVER OF ORGANIC MATTER IN PERMAFROST SOILS

Mikutta Robert^[1], Shibistova Olga^[1], Meyer-Stüve Sandra^[1], Marschner Bernd^[2], Guggenberger Georg^[1]

^[1]Leibniz Universität ~ Institut für Bodenkunde ~ Hannover ~ Germany ^[2]Ruhr-Universität Bochum ~ Geographisches Institut ~ Bochum ~ Germany

About 1600 Gt of organic C (OC) is stored in permafrost-affected soils, representing 21 to 27% of the world's OC. Facilitated permafrost thawing and active layer thickening in pan- and subarctic environments have raised concerns about the release of formerly stabilized C and the positive feedbacks on global warming. The response of permafrost-affected tundra soils to climate change will strongly depend on the amount of labile vs. stable OC stored in different horizons (e.g., active layer, cryoturbated horizons, permafrost) and the respective composition of organic matter (OM). In this study we focus on the turnover and composition of OM in permafrost-affected, cryoturbated tundra soils of the Siberian subarctic. Soils of three different tundra types, namely 'grass', 'tussock grass' and 'moss-shrubby' tundra, were sampled along a North-South gradient near the Kolyma river in Eastern Siberia. In each tundra type, we analyzed the contribution of particulate vs. mineral-associated OC in all main soil horizons following density fractionation with sodium polytungstate (1.6 g cm⁻³). Organic matter in each fraction was characterized by stable isotope composition (¹³C, ¹⁵N) and analysis of the lignin content (CuO oxidation). The apparent age of OM in these fractions was determined by AMS-¹⁴C dating, and the potential OM decomposability by aerobic incubation. The information about the functional and molecular composition of OM was related to apparent and potential turnover rates, providing new evidence about the role of abiotic factors (temperature, anaerobiosis) vs. OM quality and mineral protection for the bioavailability of OC in permafrost soils.

A COMPARISON OF RADIOCARBON AGES IN ORGANIC CARBON OF CHARCOAL AND PARTICLE-SIZE FRACTIONS IN A SANDY SOIL FROM SOUTH-EAST AUSTRALIA.

Hobley Eleanor^{*[1]}, Willgoose Garry^[1], Frisia Silvia^[2], Jacobsen Geraldine^[4]

^[1]University of Newcastle ~ Environmental Engineering ~ Newcastle ~ Australia ^[2]University of Newcastle ~ Geology ~ Newcastle ~ Australia ^[3]Australian Nuclear Science and Technology Organisation ~ Radiocarbon ~ Sutherland ~ Australia ^[4]Australian Nuclear Science and Technology Organisation ~ Accelerator Mass Spectrometry ~ Sutherland ~ Australia

Radiocarbon concentration of charcoal and 3 particle-size fractions (PSFs) ("macro": 2000–200 μm , "micro": 200–60 μm , and "mineral-associated OC, MAOC": < 60 μm) were compared at 4 depths to bedrock on a sandy tenosol from SE-Australia. In the topsoil (0–30cm), all PSFs were modern, although there was a slight depletion (1.3 - 1.6 pmC) with decreasing size. The charcoal from this depth was 85 years old, depleted by over 10 pmC compared with PSFs. At 30–60 cm charcoal was 2540 years old, over 12 times as old as the youngest fraction. At this depth, micro-OC was older (550 years BP) than the other PSFs, (macro: 205 years BP, MAOC: 330 years BP). Charcoal fragments were visible and possibly accumulated in the micro-fraction, inducing its lower C14 concentrations. Assuming an age intermediate to the macro and MAOC fractions for non-charcoal OC in the micro fraction, the amount of charcoal required to account for the shift in C14 dates would be 12.4% ($\pm 2.4\%$). The trend of oldest OC in the micro-fraction continued at 60–100 cm, but no charcoal was visible. Near bedrock (100–120 cm) C14 concentrations of the three PSFs did not differ significantly: all PSFs were ca. 1270 years old. Our results confirm the hypothesis that charcoal is a highly recalcitrant form of SOC. However, C14 ages of the PSFs at 100–120 cm were half those of charcoal at 30–60 cm, indicating that charcoal does not contribute to OC stabilisation near bedrock in this soil.

S07.06a -6

**BIOLOGICAL PATHWAYS OF LITTER DECOMPOSITION AND SOIL CARBON STABILIZATION:
RETHINKING THE ROLE OF PLANT INPUTS AND MICROBIAL COMMUNITIES**

Grandy A. Stuart*^[1], Wickings Kyle^[1]

^[1]University of New Hampshire ~ Natural Resources and Environment ~ Durham, NH ~ United States

Microbes are the engines that drive decomposition, but to what degree are decomposition and soil organic matter (SOM) formation dependent upon the structure and function of unique microbial communities? Historically, theories on the formation of soil organic matter have focused on two major paradigms. The first focused on the decomposition of litter inputs and the influence of litter quality therein (e.g. lignin/N ratio). The other focused on the abiotic and chemical alteration of litter inputs that can increase the chemical complexity of SOM. More recent conceptual developments and experimental evidence increasingly point to a significant direct contribution of microbially-derived products to stable SOM formation. This new model has implications that may overturn these decades-old paradigms: 1) changes in the molecular structure of decomposing plant litter are directly dependent upon decomposer community dynamics; 2) the molecular chemical diversity of microbial cells, metabolites, and transformation products – rather than the chemistry plant litter inputs – may be the origin of the molecular diversity of SOM; 3) the sorption of microbially-derived products on minerals may be the ultimate source of stable SOM; and 4) conditions that influence microbial processing and sorption (e.g. soil mineralogy, temperature, and microbial community structure) could have an overriding effect on SOM formation. This talk will explore my lab's current and future efforts to understand how decomposer communities influence SOM formation.

Physical fractionation procedures isolate soil fractions of different functions. We aimed at determining (1) factors that control the distribution of organic carbon (OC) over density fractions and (2) how soil OM stability relates to those fractions. We sampled 12 European sites under different land use, climate, and soil types, taking 10 replicate soil cores per site. Carbon and nitrogen concentrations, ^{13}C , and ^{14}C content were measured in three density fractions (free light fraction, fLF, occluded light fraction, oLF, heavy fraction $>1.6 \text{ g cm}^{-3}$, HF). Carbon mineralization rates were determined in the laboratory. The contribution of LF to OC stocks varied between 5 and 65% in the 0–10 cm layer and decreased with soil depth. Root litter seems to be the most important source for fLF-OC, while dissolved organic carbon determined the depth distribution and the age of HF-OC in total profiles. OC of all fractions of the upper soil layer was young and mineralization rates were related to OC in all fractions. Larger differences between fractions occurred in deeper soil layers where especially HF-OC became older. CO_2 release per g OC in samples as well as ^{14}C data were related to fLF-OC in subsoil layers, indicating larger microbial activity with more input of new organic material. Land use affects the distribution of OC across fractions by selection of different plant functional types and soil disturbance or mixing by plowing. As mineralization rates are linked to fLF-OC, distribution of belowground carbon input strongly influences carbon dynamics in subsoils.

IS STABLE ORGANIC MATTER PHYSICALLY PROTECTED ? AN APPROACH USING LONG TERM BARE FALLOW EXPERIMENTS

Paradelo Celso Remigio^{*[1]}, Claire Chenu^[1], Folkert Van Oort^[2]

^[1]AgroParisTech ~ Bioemco ~ Grignon ~ France ^[2]INRA ~ Pessac ~ Versailles ~ France

Disentangling the different processes responsible for the stabilization of soil organic matter on the long term is especially difficult. The long term bare fallow of Versailles (42 plots) offers a double opportunity: (i) after 80 years of bare fallow most of total organic carbon is kinetically stable; and (ii) the bare fallow plots have been amended annually with different treatments leading to very contracted soil structure, at least visually. We used this experiment to analyse the impact of soil structure on the amount of stable organic carbon. Reference, CaCO₃ or KCl plots soil were studied. Soil macroaggregation and microaggregation as well as C contents and stocks in the upper 20 cm layer were quantified. CaCO₃ plots soil exhibited a more aggregated soil structure than KCl and reference plot, although the differences were small for microaggregation. Only small differences were found in the C stocks between treatments, indicating that the better structure in the carbonate plots did not provide for much protection against organic matter mineralization in the long term. Two hypothesis are proposed, not exclusive: (i) at this time scale C is rather protected by adsorption to minerals and (ii) stable C is protected at finer spatial scales, i.e. in clay-size aggregates.

S07.06b -3

STABILIZATION OF ORGANIC MATTER BY ADSORPTION TO AND COPRECIPITATION WITH FERRIHYDRITE

Chen Chunmei^{*[1]}, Aufdenkampe Anthony^[2], Dynes James^[3], Wang Jian^[3], Regier Tom^[3], Sparks Donald^[1]

^[1]University of Delaware ~ Plant and Soil Sciences ~ Newark ~ United States ^[2]Stroud Water Research Center ~ none ~ Avondale ~ United States ^[3]Canadian Light Source ~ none ~ Saskatoon ~ Canada

Intimate association with mineral phases has been recognized as a fundamental mechanism of stabilizing organic matter (OM) against biological degradation, and is therefore a major control for soil carbon storage. Ferrihydrite, because of its ubiquitous occurrence in the environment and its high surface area, contributes significantly to the sorption of OM and protects it against microbial degradation in soils and sediments. In addition, ferrihydrite often forms in the presence of dissolved organic matter in the natural environment, which leads to coprecipitation of OM with ferrihydrite. However, the extent and mechanisms of OM adsorption to or coprecipitation with ferrihydrite, and the consequences of such reactions for the properties of sorbed versus coprecipitated OM remain largely unknown. In this study, we compared adsorption and coprecipitation with dissolved organic matter from a forest litter layer. The objectives of this study were (1) to compare OM loading on ferrihydrite via adsorption and coprecipitation; (2) to examine the chemical fractionation of OM and the mechanisms of organo-ferrihydrite complex formation associated with these two processes using NEXAFS and FTIR spectroscopy; (3) to assess the stability of sorbed and coprecipitated OM against desorption and thermal treatments; and (4) to study the spatial distribution, macromolecular structure and chemical composition of sorbed and coprecipitated OM at the nanometer-scale by scanning transmission X-ray microscopy (STXM). This study will improve our understanding of the coprecipitation of dissolved organic matter with iron precipitates, which is an important process for carbon accumulation in natural systems.

RELATION BETWEEN LIGNINS AND ALIPHATIC CONSTITUENTS IN SOILS HIGHLIGHTED BY AN ISOLATION PROCEDURE: IMPLICATION FOR LIGNIN DEGRADATION ?

Thevenot Mathieu^{*[1]}, Dignac Marie-France^[2], Bahri Haithem^[3], Lapierre Catherine^[4], Pollet Brigitte^[4], Bardoux Gérard^[2], Rumpel Cornelia^[2]

^[1]Laboratoire Génie-Civil et géo-Environnement ~ Université Lille 1 ~ Villeneuve d'Ascq ~ France ^[2]UMR Biogéochimie et Ecologie des Milieux Continentaux ~ INRA-CNRS-Université Paris 6 ~ Thiverval-Grignon ~ France ^[3]Laboratoire de génie rural ~ INRGREF ~ Ariana ~ Tunisia ^[4]UMR 1318 INRA-Agroparitech ~ Institut Jean-Pierre Bourgin ~ Versailles ~ France

Lignins are a major aromatic constituent of plant biomass. Lignins were suggested to contribute to stable C in soils. Recent studies, using CuO oxidation, identified two kinetic lignin pools in soils. However, the CuO method releases phenol monomers from the less condensed part of lignins only. The milled wall enzymatic procedure was developed to isolate a fraction of intact lignin polymer (MWEL). We used this technique to study the dynamics of isolated soil-MWEL in the experimental field of "les Closeaux", where a C3/C4 vegetation succession induced a natural ¹³C labelling of soil organic matter. We isolated MWEL from maize (C4) and wheat (C3) plants, from a wheat-soil and a soil after 9-years maize cropping. Lignin yields, elementary composition, ¹³C-isotopic signature and chemical structure were analysed. ¹³C Nuclear Magnetic Resonance (NMR) spectroscopy revealed that soil-MWEL contained aliphatic compounds, while plant-MWEL were associated with polysaccharides. The presence of aliphatic moieties in soil-MWEL could explain the decrease of their O/C ratio and the increase of their H/C ratio compared to the plant-lignins. Close association of lignins with hydrophobic aliphatic constituents in soils could limit their degradability. The evolution of the ¹³C-isotopic signature of the MWEL-lignins from soil was compared to those of the lignin monomers released by the CuO method and of the bulk SOC. We conclude that lignin fate in soil is not only dependent of their chemical structure but also related to their interactions in soil with other compounds, which nature and variability remain to be defined.

S07.06b -5

HUMIN: IS IT A REALLY A HUMIC SUBSTANCE?

Hayes Michael H.b.^[1], Swift Roger^{*[2]}

^[1]Chemical and Environmental Sciences ~ University of Limerick ~ Ireland ^[2]University of Queensland ~ Alliance for Agriculture and Food Innovation ~ Queensland ~ Australia

The classical humic fractions are differentiated on the basis of solubilities in aqueous media. By these definitions, humin is a significant and highly-resistant soil humic component which is insoluble in both acidic and basic media. Its lack of solubility and extractability in aqueous media has greatly limited compositional studies of humin. In this study soils were exhaustively extracted with aqueous media at pH values of 7, 10.6, and 12.6, and 0.1M NaOH + 6M urea. Separations at the different pH values represent differences in solubility and charge densities of the humic components. Solid state CPMAS ¹³C NMR and functional group analyses studies have shown that all of these fractions have compositions typical of humic substances. The substantial amount of organic matter still remaining in the soil is, by definition, humin. Following the exhaustive extraction, the soil was dried then extracted with DMSO and concentrated H₂SO₄ (94:6) which solubilised and extracted the humin. Diffusion edited proton NMR spectra of the isolated humin show that it is composed of predominantly aliphatic materials comprised mainly of plant lipids, waxes, and hydrocarbon structures with small amounts of carbohydrates and peptides. There is very little evidence of aromatic or lignin-derived structures in this fraction. On this evidence humin does not satisfy the classical definitions for humic substances.

S07.06b -6

MINERAL-ASSOCIATED SOIL C STABILIZATION IN THE 80 YEARS BARE FALLOW CHRONOSEQUENCE

Vasilyeva Nadezda^[1], Van Oort Fok^[2], Chenu Claire^{*[3]}

^[1]CNRS Bioemco ~ Soil organic matter group ~ Thiverval-Grignon ~ France ^[2]INRA ~ Pessac ~ Versailles ~ France

^[3]AgroParisTech, Bioemco ~ Soil organic matter group ~ Thiverval-Grignon ~ France

Rates of soil organic matter decomposition, soil organic carbon (SOC) stabilizing processes and their relative strength are still poorly understood. Bare fallows in long-term agronomic experiments, provide unique opportunities to understand SOC decay and stabilization, as changes in amount and quality of the initial SOC can be followed with no contribution of fresh organic matter inputs. To understand the importance of SOC stabilization mechanisms we faced questions: (i) what are the rates of depletion for separable SOC fractions? (ii) What is the final stable SOC pool comprised of? We studied the chronosequence of samples from a long-term experiment of bare fallow in Versailles, France. Soil samples, taken from the 0-20 cm depth in 1929, 1939, 1949, 1962, 1972, 1991, 2008. We obtained fractionation: clay <2 µm, silt-size (2-50 µm) light (LF) and heavy fractions (HF), fine sand (50-200 µm) POM and HF, and coarse sand (>200 µm). We measured C, N and d13C concentrations as well as dissolved organic carbon. The studied soil was polluted by charcoal during the war period in 1940s. To take this into account the decay of SOC pools excluding charcoal was modeled using C/N ratio development in the chronosequence. Results show the major SOC stabilization mechanism in long-term is association with minerals. In particular, clay-size minerals had the strongest ability to stabilize SOC, whereas clay-associated labile SOC pool was the slowest among others. C turnover rates follow the order: DOM, POM (5-10yr) < LF (15-20 yr) < silt HF (20-30 yr) < clay (30-40 yr).

SOIL AGGREGATE- AND PARTICLE-ASSOCIATED ORGANIC CARBON AND NITROGEN POOLS UNDER DIFFERENT LAND USES IN ETHIOPIA

Singh Bal Ram^[1], Gelaw Aweke*^[1], Lal Rattan^[2]

^[1]Norwegian University of Life Science (UMB) ~ Department of Plant and Invironmental Sciences (IPM) ~ Aas ~ Norway

^[2]The Ohio State University ~ School of Environment and Natural Resources ~ Columbus ~ United States

Soil aggregation is the main process whereby soil organic carbon (SOC) and total nitrogen (TN) are retained in soils. Thus, aggregate and particle associated SOC and TN in surface and sub-surface layers were estimated following standard procedures for five land uses on a watershed in Ethiopia. The land uses were rainfed crop production (RF), agroforestry (AF), grazing/pasture (OP), silvopasture (SP), and irrigation (IR) with five replications each. Land use had significant effects on soil aggregation and SOC concentrations associated with macroaggregates ($P = 0.0017$) in the 0-10 cm layer. OP had the highest water stable aggregates and SOC associated with macroaggregates (19.95 gkg^{-1}) which were significantly higher ($P < 0.0001$; $P = 0.0017$) than those in other land uses. SOC associated with both macro and microaggregates decreased with depth. Macroaggregates contained higher SOC concentrations than microaggregates in both layers and all land uses. AF had the highest SOC associated with microaggregates indicating the potential of AF in stabilizing SOC. TN followed a similar trend to that of SOC. Land use also had significant effects on SOC and TN concentrations associated with sand particles. OP had the highest SOC and TN associated with sand particles. OP, SP and AF had higher SOC concentrations associated with clay particles showing the potentials of grass and tree based systems in stabilizing SOC. Key words: Aggregation, C-sequestration, C-sink capacity, land use, Ethiopia

EFFECTS ON SOIL FERTILITY AND CROP YIELD**

Ventrella Domenico*^[1], De Giorgio Donato^[1], Rinaldi Michele^[1]

^[1]Agricultural Research Council ~ Research unit for cropping systems in dry environments ~ Bari ~ Italy

Management of crop residues, crop rotation and soil tillage are important agronomic practices that can conserve or greatly influence the soil fertility in term of content of soil organic carbon and crop productivity. In order to determine long-term dynamics of such practices, long-term field researches have been established in Southern Italy by the Research unit for cropping systems in dry environments of the Agricultural Research Council. At the experimental farm in the Northern part of Apulia Region, three long-term trials are currently being carried out on clay-loam soil since 1977, 1989 and 1990. A series of treatments on the effects of burning or incorporation of crop residues, soil tillage and crop rotations based on winter durum wheat have been compared. At the experimental farm of CRA-SCA in the central part of Apulia, since 1976 almond plants have been submitted to different treatments consisting of weed management based on chemical weeding, weed mulching, weed incorporation through minimum and conventional tillage. In general the incorporation of straw and stubble showed slight increments in organic soil matter respect to burning. The best results for soil organic carbon and soil quality were obtained when residual incorporation included a treatment with additional mineral nitrogen. The tillage method did not influence the organic carbon, total nitrogen and available phosphorous contents of the soil, nor did crop rotations. In the almond trial, no-tillage with green mulching determined a general increase of TOC with respect to other treatments.

SOIL ORGANIC CARBON TRENDS IN ARABLE SOILS: INTERPRETING IMPERFECT EVIDENCE FROM EXPERIMENTS AND MAKING PRACTICAL MANAGEMENT DECISIONS

Powlson David^[1], Whitmore Andy^[1], Coleman Kevin^[1], Macdonald Andy^[1], Glendining Margaret^[2]

^[1]Rothamsted Research ~ Sustainable Soils & Grassland Systems ~ Harpenden ~ United Kingdom ^[2]Rothamsted Research ~ Biomathematics & Bioinformatics ~ Harpenden ~ United Kingdom

Soil organic carbon (SOC) content in arable soils in temperate regions changes slowly in response to changing management. Consequently long-term experiments are an essential tool to detect these changes. But results require careful interpretation, taking account of any inherent limitations in experiments. A review of the impacts of cereal straw incorporation on SOC, based on 25 long-term experiments in three continents, showed (as expected) a general trend towards decreased SOC where straw was removed. However, the decreases were small (usually <10%) and only statistically significant in a quarter of cases. Yet there is evidence that small changes in total SOC can have significant effects on soil physical properties relevant to crop growth, such as aggregate stability, water infiltration and ease of tillage. Such findings have practical and policy implications for decisions on the removal of straw as a biofuel feedstock; the impact on soil quality may be significant even if the decrease in SOC is small. SOC content moves from one quasi-equilibrium value to another under the influence of management practices; it does not increase or decrease indefinitely. This, and indirect and off-site impacts of SOC changes that are sometimes overlooked, are limitations to the potential for soil C sequestration to mitigate climate change. Nevertheless, practices to increase or maintain SOC are important for soil functioning and sustainable agriculture. A combination of long-term data, measurements of specific SOC fractions, and C modelling are important elements for constructing tools for translating academic understanding of SOC into practical decision making.

LONG-TERM EFFECTS OF MINERAL FERTILISERS AND ORGANIC MANURES ON SOIL ORGANIC MATTER AND CROP PRODUCTION

Macdonald Andrew*^[1], Poulton Paul^[1]

^[1]Rothamsted Research ~ Sustainable Soils and Grassland Systems Department ~ Harpenden ~ United Kingdom

The long-term experiments at Rothamsted date from 1843 when a series of field experiments began to examine the effect of inorganic fertilisers (N, P, K, Mg & Na) and organic manures, including Farmyard Manure (FYM), on crop production and soil fertility. These included studies on winter wheat (Broadbalk 1843) and spring barley (Hoos Barley 1852). Long-term additions of FYM have substantially increased the soil organic matter (SOM) content of the plough layer (0-23cm) on some of the plots on Broadbalk and Hoosfield, but for many years this extra SOM had little benefit on grain yields compared with crops given inorganic fertilisers. However, with the introduction of cereal varieties with greater yield potential, and the appropriate use of fungicides, larger yields were achieved on soils with greater SOM plus mineral N. Currently on Broadbalk, yields of first wheats after a 2-year break given FYM plus additional N fertiliser are similar to the greatest yields achieved with mineral fertilisers alone. In contrast, yields of continuous spring barley on Hoosfield given FYM for many years, with or without additional fertiliser N, are often greater than can be achieved by mineral fertilisers alone. The reasons for this almost certainly include effects of SOM on nutrient supply (especially N), soil structure, water retention and root growth. The Rothamsted Long-term Experiments are a useful resource with which to further examine the effects of organic manures and soil organic matter on new, potentially higher-yielding, cereal varieties in future.

SHORT- AND LONG-TERM EFFECTS OF DIFFERENT ORGANIC CARBON INPUTS ON CROP YIELDS AND SOIL FERTILITY EVALUATED IN SWEDISH LONG-TERM FIELD EXPERIMENTS

Kätterer Thomas*^[1], Kirchmann Holger^[1], Börjesson Gunnar^[1]

^[1]SLU, Swedish University of Agricultural Sciences ~ Soil and Environment ~ Uppsala ~ Sweden

Crop residues and organic amendments applied to soil affect crop yields depending on their nutrient concentration. However, short-term effects may differ from long-term effects due to feedbacks on soil fertility. Based on results from Swedish long-term field experiments we compared effects on crop yields and soil organic matter stocks following continuous applications of high-N organic materials such as farmyard manure, sewage sludge, household compost and green manure with those after application of low-N organic materials such as straw, peat and sawdust in combination with or without mineral N fertilization. Generally, nitrogen-rich manures caused a yield increase whereas nitrogen-poor organic amendments caused a two-phase yield response; initially declining trends in crop yields converted to increases exceeding those in the control after about three decades. Combinations of low-N amendments and N fertilizer resulted in higher yields than only N fertilization. Higher soil organic matter contents induced by combining organic amendments and N fertilization are mainly explained by a higher root input. Thus, farming practices that lead to increased crop yields will also result in increasing soil organic matter stocks. This positive feedback due to N fertilization can probably also explain why soil organic matter content can be maintained on many Swedish farms even without applying manure. In more extensive arable systems, however, manure application and/or perennial crops in rotation are necessary for maintaining soil fertility. We emphasize that in addition to the short-term fertilizer value of organic amendments, the long-term effects on soil fertility should be considered.

S07.07a -5

SUSTAINABILITY OF CROPPING SYSTEMS IN NUTRIENT LIMITING CONDITIONS IN A MEDITERRANEAN ENVIRONMENT

Berti Antonio^{*[1]}, Morari Francesco^[1], Giardini Luigi^[1]

^[1]University of Padova ~ Dep. Environmental Agronomy and Crop Sciences ~ Legnaro (PD) ~ Italy

In the recent years the average amount of fertilisers used in Italy has markedly decreased as the result of external constraints, such as the increase of fertilizer costs and the introduction of regulations to limit phytonutrient losses. This tendency can have positive effects, promoting a more efficient use of production factors and improving environmental quality, but create a concern on which amount of reduction can be achieved maintaining a long-term sustainability of cropping systems. Soil can act as a buffer in the short term, supplying an input deficit, but its ability to sustain crop growth is limited. Deployment of soil nutrient stock has a consistent impact on other soil traits, mainly related to SOC content (eg. soil structure, water retention, C sequestration). Long-term experiment can give important information on these subjects, allowing to highlight even subtle changes in soil fertility and crop production trends. The present contribution aims to summarize the results obtained in a long-term experiment where different cropping systems and intensification practices has been compared since 1962. The sustainability of the systems has been evaluated in terms of nutrient balances, SOC dynamic and soil quality indicators (eg. aggregate stability, water retention). The implication of the observed changes and the potential effects of actual regulations on nutrient supply are then discussed.

LONG-TERM EFFECTS OF AGRONOMIC PRACTICES ON SOIL ORGANIC CARBON AND CROP PRODUCTIVITY IN THE INTERNAL HILLS OF SICILY

Cosentino Salvatore Luciano*^[1], Scalici Giovanni^[1], Ambra Riccardo^[1], Guarnaccia Paolo^[1], Copani Venera^[1]

^[1]Università degli Studi di Catania ~ DISPA ~ Catania ~ Italy

In the hilly areas of Mediterranean environment the high intensity of autumnal rains determines high level of soil erosion losses in agricultural field reducing the soil fertility in the long run. In Sicily region this phenomenon have been emphasized by the crop management and by the orography of the territory. The experimental farm of UNICT for the collection of surface runoff is located in the c.da Manca di Geracello, Enna (550 m a.s.l., 37° 21'N, 14°16'E). The establishment consists of 12 plots. In the last sixteen years (1996-2011) the study of the impact assessment of various herbaceous cropping systems, both in terms of crop rotation (one crop, alternating different crops), crop habit (annual or perennials), types of soil tillage (traditional, minimum tillage, no tillage) on the dynamics of soil organic matter was carried out. The soil organic matter content, according to the depth of measurement (0-30 and 31-60 cm), the portion on the plot where the sample was taken (high, medium, low), and the season (winter and summer), was found significantly different according to the different cropping systems. The variation of organic matter in time was depending upon the soil tillage (plowing or not and sod seeding), the habitus of crop (annual or perennial). In the case of perennial the organic matter increased from 1.2 to 2.2%. The sod seeding allowed to take the organic matter around 1.8-2.0%

CONTRIBUTION OF AGRICULTURAL CROP RESIDUE-C TO STABILIZED SOIL ORGANIC MATTER

Voroney Paul^[1], Beyaert Ron^[1]

^[1]University of Guelph ~ School of Environmental Sciences ~ Guelph ~ Canada

*Inputs of crop residues in agricultural soils are the primary means of sustaining soil organic matter levels. A field study was set out in 1990 to quantify tillage effects on crop residue-C decay and on its subsequent formation of stable soil organic matter. At crop harvest, ¹⁴C-labeled, above-ground residues representative of common agricultural crops grown in southern Ontario, corn (*Zea mays* L.), soybeans (*Glycine max* L.), winter wheat (*Triticum aestivum* L.), winter rye (*Secale cereale* L.) and tobacco (*Nicotiana tabacum* L.), were added to soils managed under conventional (CT) mouldboard plough-disc and conservation tillage (RT). Recovery of crop residue derived-C was measured as ¹⁴C remaining in the upper 40 cm depth, and expressed on an equivalent soil mass. Kinetic analysis of the pattern of crop residue decay showed that under CT the labile component was larger and decayed faster compared with RT. This suggests that incorporated residues were exposed to a more favorable environment for microbial activity compared with residues left on the soil surface. Averaged over all crops, the resistant component contributing to formation of stable soil organic matter was 50.3% larger under RT, though it decayed at a slightly faster rate, $t_{1/2} = 7.3$ y, vs $t_{1/2} = 8.6$ y under CT. While these results confirm the benefits of adoption of conservation tillage practices on slowing the decay of the labile component of crop residues, tillage practices had no effect on the proportion of residue-derived C becoming stabilized soil organic matter in the long term.*

Soil organic carbon represents an important carbon pool guaranteeing the numerous soil functions such as soil nutrient cycling and carbon sequestration. Both, organic farming and reduced tillage can enhance SOC levels, but there is a lack of information concerning the combined effects of reduced tillage under organic farming. We assessed the effects of reduced tillage (chisel/"stubble cleaner" = Stoppelhobel in German) versus an ordinary plough system over a six year crop rotation under temperate climate on a clayey loam in a ley rotation. Yields were lower during the conversion period to reduced tillage, but were higher in the second experimental phase, rendering to an all over yield increase of 11% compared to the plough system. SOC levels in the 0-10 cm soil depth increased by 17% (3.7 g kg⁻¹ soil), soil microbial biomass by 37% and dehydrogenase (DHA) was enhanced by 57% in reduced tilled plots. While no changes of SOC were measured in the soil layer 10-30 cm, DHA was increased by 16% in the soil layer 10-20 cm. SOC increase accounted for 1.3 t carbon sequestration ha⁻¹ year⁻¹. An improved climate impact model based on IPCC, including also SOC gains, revealed over 2 t CO₂ capturing ha⁻¹ year⁻¹ in the reduced tillage system, whilst in the plough system only 0.55 t of CO₂ ha⁻¹ year⁻¹ were fixed in the soil (long term storage). We conclude that reduced tillage systems under organic farming in particular have a high sink potential for CO₂, while improving productivity and soil fertility.

DOES NO TILL INCREASE SOIL CARBON SEQUESTRATION ON THE LONG-TERM IN EUROPEAN TEMPERATE CLIMATE? ANALYSIS OF A LTE IN NORTHERN FRANCE

Dimassi Bassem*^[1], Bruno Mary^[1], Jérôme Labreuche^[2]

^[1]INRA ~ EA ~ Laon ~ France ^[2]Arvalis-Institut du Végétal ~ EA ~ Boigneville ~ France

Many studies have shown that reduced tillage systems such as shallow till (ST) and no till (NT) can be efficient strategies to increase soil organic carbon (SOC) compared to inversion tillage (IT), with a mean rate of sequestration of 100 to 200 kg C ha⁻¹ per year (Lal, 2004; IPCC, 2007). However, several recent meta-analyses (e.g. Angers et al, 2008; Luo et al, 2010; Virto et al, 2011) add controversy, showing that C sequestration can vary from significantly positive to negative values. Long term experiments (LTE) are invaluable tools to bring reliable conclusions on these effects. We examined one of the oldest LTEs in the world, located at Boigneville in Northern France. Three tillage systems have been differentiated for 40 years, in a maize–wheat rotation: NT, ST tilled down to 5-8 cm depth and IT tilled down to 25 cm by mouldboard ploughing. SOC and SON (nitrogen) contents were measured every 4 years since 1970. Bulk density was measured in some years before 1990 and regularly from 2000 onwards. SOC stocks were calculated on the basis of constant soil mass. The first results obtained show that SOC increased slightly versus time in all treatments. The increase was faster in NT and ST than IT during the first 10-15 years, but slower (even negative) during the last 30-40 years. After 40 years, SOC distribution in soil profile was very different between treatments, suggesting different turnover times. These results will be thoroughly examined as well as the uncertainty on SOC estimates.

**LONG-TERM EFFECTS OF DIFFERENT FORMS OF ORGANIC FERTILIZERS AND TILLAGE
ON SOIL ORGANIC CARBON AND CROP YIELDS**

Sinaj Sokrat^[1]

^[1]Agroscope-ACW ~ Plant nutrition ~ Changins ~ Switzerland

Easier access to synthetic fertilizers and specialization of farms led to the decrease in the use of manure on stockless farms and to the simplification of crop rotation. The removal of manure causes a well documented decline in the content of soil organic carbon (SOC). The techniques of soil conservation (straw restoration, green manure and reduced-tillage) are known for their positive effects on the storage of SOC. They could potentially compensate for the absence of manure. However, these techniques must be integrated in sound cultural systems and their effectiveness must be evaluated. To answer these questions, two long-term field experiments were established in 1976 and 1997 by the Swiss Research Station Agroscope ACW. Both experiments were conducted on a Calcaric Cambisol with a crop rotation alternating spring and winter crops and including cereals, rapeseed and maize over a period of five to six years. The experiments were designed to compare the effects of manure and of three techniques for SOC conservation on SOC content and crop yields. The results show that the three soil conservation techniques and manure amendments to the usual dose (12 t cattle manure ha⁻¹ every year and / or 60 m³ cattle slurry manure ha⁻¹ every 3 years) were not sufficient, under Changins conditions, to maintain the initial level of SOC. In addition, the three soil conservation techniques were as effective as manure used at usual doses for storing SOC. These techniques showed lower potential yields and / or required increased nitrogen fertilizers.

LONG-TERM TILLAGE TREATMENTS IMPACT ON THE PROPERTIES OF A HEAVY CLAY SOIL: INTERACTIONS BETWEEN ORGANIC CARBON, CLAY CONTENT, MICROBIAL ACTIVITY AND PHYSICAL PROPERTIES.

Boivin Pascal^[1], Fontana Mario^[1], Lamy Frederic^[1], Maeder Paul^[2], Berner Alfred^[2]

^[1]University of applied sciences of western Switzerland ~ Agronomy ~ Genève ~ Switzerland ^[2]FIBL ~ Soil Science Group ~ CH 5070 - Frick ~ Switzerland

This study reports the changes in soil properties and crop yield observed after a 10 yearlong tillage experiment driven in Switzerland on a heavy clay soil. Reduced tillage (RT) and conventional tillage (CT) were compared based on yield monitoring, and soil sampling at three depths, namely topsoil, below the RT hardpan, and below the CT hardpan. Because of the well-known interactions between soil physical, chemical and biological properties, all analyses were performed together. The physical properties were determined from shrinkage analysis, thus making distinction between soil plasma and structural pores properties, and discriminating the role of pre-existing variability in soil constituents from the impact of tillage induced changes, based on analysis of covariance. After removal of the natural clay gradient effect, the results showed mostly a significant increase of SOC in RT compared to CT in topsoil. ANCOVA showed that the SOC increase determined most of the other soil properties such as increased porosity and structural porosity, increased available water and air, as well as increased microbial activity and related properties. These changes are modulated according to depth. After scaling of the soil properties with respect to SOC, an additional significant effect of the tillage treatment is revealed, that we attribute to mechanical impact of the tillage. Unsurprisingly, the yield monitoring showed a continuous increase of the production in the RT plots. On this heavy clay soil, the RT shows, therefore, promising results, and the observed changes are largely determined by the changes in SOC.

IMPACTS OF ARABLE MANAGEMENT ON SOIL ORGANIC CARBON AND CROP PARAMETERS

Spiegel Heide^{*[1]}, Dersch Georg^[1], Hösch Johannes^[1], Baumgarten Andreas^[1], Aichberger Karl^[2]

^[1]Austrian Agency for Health and Food Safety ~ / ~ Vienna ~ Austria ^[2]Austrian Agency for Health and Food Safety ~ / ~ Linz ~ Austria

Long term field experiments are indispensable to quantify the effects of changes in arable soil management such as tillage, organic and mineral fertilisation and the management of crop residues on different soil and crop parameters. The Austrian Agency for Health and Food Safety (AGES) runs field experiments since more than 20 years. The arable practices under study are: • different tillage systems ("conventional", "reduced", minimum) • different amounts and forms of nitrogen (N) and phosphorus (P) fertilisation • application of different composts (biowaste compost, green waste compost, cattle manure compost and sewage sludge compost) • management of crop residues (incorporation, removal) The results indicate that the maintenance of soil organic carbon (SOC) at the investigated sites is only possible, if tillage is reduced to a minimum and crop residues (cereal grain straw, maize stover, sugar beet leaves) remain on the field. 18 years of compost application result in a significant increase of SOC compared to mineral fertilisation. SOC decreases occur in the long-term with frequent tillage (two times a year and more). This is also the case, if crop residues are removed every year, or if crops without or only few residues (e.g. silo maize, potatoes) dominate the crop rotation, even though the residues normally remain at the field. The effects of different arable management practices on crop yields and quality will be discussed.

^[1]TU-Dresden ~ Institute of Soil Science and Site Ecology ~ Dresden ~ Germany

Chronosequences as a space-for-time substitution are an important tool to assess temporal dynamics of soil fertility. This tool was used to study land-use systems without crop rotation in Ecuador based on the assumption that agricultural land-use implies a negative trend over time on soil fertility and crop productivity. Thus, effects of land-use change and subsequent dynamics of total and plant available macronutrients and soil organic carbon (SOC) were analyzed. Based on farm surveys three main land-use types pasture, perennial (cocoa, coffee, plantain) and annual (maize, cassava) were categorized into age classes and compared to the adjacent natural forest. Mineral soil (depth gradient 0-5, 5-10, 10-30 cm) and organic layers in the forest were sampled for the determination of soil physical (bulk density, texture) and soil chemical parameters (pH, total and plant available macronutrients). Generally, perennials had higher nutrient stocks than pastures of the same age class. SOC stocks declined directly after conversion from forest to annuals from 67 t ha⁻¹ to 56 t ha⁻¹. Pasture sites showed a slight increase of SOC stocks until the age of 30 years from 58 t ha⁻¹ to 64 t ha⁻¹ and a strong decrease to 54 t ha⁻¹ after exceeding this age. Decreasing nutrient stocks caused a reduction in productivity and the abandonment of annuals after 5-10 years and perennials after 20-30 years. Hence, the current land-use management cannot be regarded sustainable since all land-use types show negative effects on SOC sequestration and a decline in major nutrients in the long term.

In the long-term, microorganisms have a potentially important role in mediating soil fertility and plant biomass productivity. These effects were studied at the Static Fertilization Experiment Bad Lauchstädt (SFEBL), established in 1902. Previous studies have either focused on abiotic factors (accumulation or the release of SOC) or on microbial biomass and their activities. Here, we aim to bridge biotic processes and abiotic parameters by analyzing a broad set of site, management and biomass production relevant parameters. For these analyses, soil samples were taken from the SFEBL in June 2010 at the alfalfa strip [legumes (since 1926) but 25 % alfalfa since 1970] from selected treatments (unfertilized, NPK, 20 T ha⁻¹ yr⁻¹ manure, 20 T ha⁻¹ yr⁻¹ manure + NPK, 30 T ha⁻¹ yr⁻¹ manure, 30 T ha⁻¹ yr⁻¹ manure + NPK). Measured parameters include: soil bulk density, SOC, total N, labile organic C and N, microbial substrate induced respiration (SIR) biomass, and phospholipid fatty acid analysis. In addition we extracted amino acids, amino sugars, and mono-saccharides as soil quality biomarkers to evaluate their relevance and role within the carbon transformation process, when linking them with enzymatic activities as ecosystem functions of microbial biomass. Positive effects of fertilization and related contents of SOC and labile OC were reflected in plant biomass production, the total PLFA and SIR biomass, and enzymatic activities; a negative correlation was found for the colonization of alfalfa roots with arbuscular mycorrhiza and soil fungal biomarkers. Amino acids, amino sugars, and mono-saccharides responded differently to treatments.

DYNAMICS OF SOIL C FRACTIONS DURING THE CONVERSION OF SHORT-ROTATION COPPICES INTO ARABLE LAND AND GRASSLAND

Toenshoff Charlotte^[1], Wachendorf Christine^[1], Reinhold Stülpnagel^[1], Joergensen Rainer^[1]

^[1]Universität Kassel ~ Ökologische Agrarwissenschaften ~ Witzenhausen ~ Germany

Until now ecological effects of the conversion of short rotation coppices (SRC) back into arable land or grassland have rarely been examined. During conversion intensive soil tillage is performed for breaking up roots and coarse harvest residues, which remain on the sites after the harvest. It is hypothesized that reduced tillage will cause a lower mineralization of organic matter. Furthermore the mineralization intensity probably will be lower if grassland will be cultivated compared to arable crops like maize. Therefore a field trial was conducted at three former SRC sites in Northern Germany and the influence of tillage depths and following landuse on short term soil C and N dynamics was investigated. Directly and one year after the conversion the amounts of C and N in coarse roots and harvest residues (> 2mm) and different C-fractions in the fine mineral soil were compared. The incorporation of the harvest residues into the soil during the tillage increased the soil C stocks up to 20 t ha⁻¹. One year after the conversion the amount of C stored in the harvest residues have declined between 2 and 17 t ha⁻¹, nevertheless differences in SOC of the bulk soil were not significant. A density fractionation and a fractionation of water stable aggregates revealed an increase of labile C in the free particulate organic matter and in macroaggregates (250-2000µm) directly after rotary hoeing compared with the C-portions bound in these pools under the SRC. One year after conversion the C in these pools decreased again.

Within the context of Climate Change, crop management exerts a strong influence on the soil carbon (C) balance. This study aims (1) to estimate the C loss by soil heterotrophic respiration (SHR) in different residue management treatments through the establishment of their soil C budgets and (2) to compare these estimations with field SHR measurements. Three contrasted treatments were considered: Residue Export (RE), Farm Yard Manure addition (FYM) and Residue Restitution after harvest (RR). They were established in 1959 and continuously applied since then at an experimental field located in the Hesbaye region in Belgium. The soil C budget was calculated for each treatment on the basis of total soil organic C content measurements and C input data compiled since the beginning of the experiment. This allowed estimating the C loss by SHR in the different treatments. SHR measurements were performed in 2010 and 2011 to compare them with the budget-based estimations and to assess SHR sensitivity to temperature in the different treatments. The soil C budgets showed that the soil under the RR treatment was likely to undergo the biggest C loss by SHR since the beginning of the experiment. The SHR field measurements, performed 50 years after the experiment had begun, did however not show any significant difference between the SHR rates in the three treatments. Laboratory investigations (microbial biomass, basal respiration, metabolic diversity and soil fractionation) will be performed to better understand the effects of long-term residue management on soil C dynamics.

SIMULATION OF SOC DYNAMICS UNDER DIFFERENT FERTILIZING MANAGEMENT PRACTICES USING ROTH C CARBON MODEL

Francaviglia Rosa*^[1], Baffi Claudio^[2], Cassinari Chiara^[2], Nassisi Antonio^[3], Farina Roberta^[1]

^[1]Consiglio per la Ricerca e la Sperimentazione in Agricoltura ~ Centro di Ricerca per lo Studio delle Relazioni tra Pianta e Suolo ~ Rome ~ Italy ^[2]Università Cattolica del S.Cuore, Facoltà di Agraria ~ Istituto di Chimica Agraria e Ambientale ~ Piacenza ~ Italy ^[3]ARPA Emilia-Romagna, Sez. di Piacenza ~ Area Analitica Ambientale (A.A.A.) Suolo e Rifiuti ~ Piacenza ~ Italy

Soil can represent a sink for carbon sequestration if properly managed. In recent years many researchers have strengthen the importance of soil carbon sequestration in agro-ecosystems under different management practices. Aim of this paper was to evaluate the efficiency of RothC model to simulate C losses observed over 10 years of fertilization practices on a silty-loam soil cropped with a rotation including maize, tomato and alfalfa .Mineral fertilizers were always applied each year, while organic inputs (FYM and vinasse) were not applied consecutively for 5 years in correspondence of alfalfa cropping. RothC model simulated accurately SOC decrease with a linear relationship between predicted (y) and observed (x) C stocks (equation: $y = 0.527x + 31.882$; $R^2 = 0.7028$); moreover the model allowed to visualize the trend of C dynamics in presence of FYM (high increase of C), vinasse (low C losses), no organic matter added (sharp decrease and high C losses). Results point out that RothC model can provide useful information on soil carbon dynamics in cropping systems, and point out the importance of organic fertilization, together with mineral dressing, in particular FYM, in order to maintain good levels of OC in the soil. When other organic materials (e.g. vinasse) or no organic inputs were added, the model simulated a smooth and sharp decline of SOC respectively; in this last two cases soil acted as a source and not as a sink of CO₂, representing a real risk for the environment.

USING LONG TERM EXPERIMENTS TO ASSESS SOM REPRODUCTION ON ARABLE FIELDS

Franko Uwe^[1], Kolbe Hartmut^[2], Thiel Enrico^[2]

^[1] Helmholtz Centre for Environmental Research - UFZ ~ Soil Physics ~ Halle ~ Germany ^[2]LFULG ~ - ~ Leipzig ~ Germany

Soil organic matter (SOM) is one of the most important components of soil and its proper reproduction is the precondition for a sustainable use. Models can be used to forecast the development of SOM storage depending on soil properties, field management and climate elements. This is very helpful to avoid future SOM losses and subsequent soil degradation. But the optimal control of SOM reproduction would require an assessment of the current SOM levels because it is well known that too much of SOM may lead to environmental problems in terms of nitrogen leaching and trace gas emissions. Furthermore, the growing demand of bio-energy and crop based raw materials requires an assessment of a reasonable amount of OM that is necessary for SOM reproduction and cannot be allowed to leave the soil-plant system. Using the results of long term experiments (LTE) like SOM trends, OM-input, nitrogen balance and crop yield the efficiency and practicability of different approaches from models of SOM dynamics to decision support tools for the identification of an "optimal" SOM reproduction will be compared. Further we will discuss the advantages and challenges connected with the LTE-data experiments. Common problems with LTE data arise from the uncertainty of initial conditions, the assessment of observation errors and in some case the change of lab procedures over time. Results from several LTE's will be used to discuss different options for the identification of a reasonable SOM level that is applicable in advisory service for farmers.

Hydropedology combines tacit knowledge from field pedology and soil survey with process knowledge in modern soil physics and hydrology, the latter increasingly using simulation modelling of dynamic soil processes. Convincing examples of hydropedology have been presented in literature but a systematic analysis of what field pedology has to offer to hydrology appears to be lacking. Soil morphological features are important in soil classification systems as they provide unique information in terms of the location and properties of specific soil features while mixed samples for laboratory analysis only provide diluted, generalized results. Such unique features are particularly useful for hydropedology. A review will therefore be presented of the significance of: (i) soil structure descriptions; (ii), occurrence of different types of diagnostic soil horizons and effects of their vertical succession; (iii) redoximorphic features; (iv) different types of coatings; (v) occurrence of macropores, and (vi) differences in types of organic matter. Micromorphological, geophysical, spectroscopic and new soil physical techniques need to be applied. Pedological data are increasingly available in well accessible soil databases. Applications in hydropedology follow two approaches by defining: (i) continuous and class pedotransferfunctions, and (ii) conditioning of the physical flow system as simulated by models. More effort is needed to “mine” pedology and soil survey data to obtain location-specific data within soil profiles, allowing improvement of modelling dynamic flow processes in field soils. In turn, improved hydrological modelling will also help to better understand pedological processes as they operated in the past and are likely to develop in future.

S08.01a -2

CONTROLS OF SITE FACTORS AND SOIL PROPERTIES ON PREFERENTIAL WATER FLOW AND SOLUTE TRANSPORT

Jarvis Nicholas^[1], Moeys Julien^[1], Koestel John^[1], Ghafoor Abdul^[1], Larsbo Mats^[1]

^[1]SLU ~ Soil & Environment ~ Uppsala ~ Sweden

In this presentation, we will discuss the extent to which preferential solute transport in soil can be predicted from basic soil properties and site factors such as land use and management. A conceptual model of the pore system characteristics that generate preferential flow is proposed. This provides the necessary support for developing hydropedological approaches to understanding and predicting preferential flow. Several example case studies will be presented, including, i.) statistical analysis of the relationships between the shape of tracer breakthrough curves and soil properties in a small agricultural catchment, ii.) statistical meta-analyses of tracer breakthrough experiments on undisturbed soil columns published in the open literature, iii.) a qualitative synthesis of characteristic flow regimes in the major soil types of the world based on a review of the literature, and iv.) the development and testing of pedotransfer functions for model parameter estimation in the dual-permeability model MACRO, and their use in pesticide risk assessment.

^[1]University of Naples Federico II ~ DISSPAPA ~ Portici (NA) ~ Italy ^[2]Italian National council of Research ~ ISAFOM ~ Ercolano (NA) ~ Italy

Diagnostic horizons and diagnostic properties have a fundamental importance for soil classification (e.g. WRB, Soil Taxonomy) and also for applications in pedology (e.g. land evaluation). Then soil databases (and soil maps) typically contain information regarding the presence and thickness of diagnostic horizons. Despite these evidences, their importance in relation to hydrological processes remains to some extent unproven. Calcic horizons are subsoil horizons formed after the migration of calcium carbonate (generally) from surface horizons. Its classic explanation is based on the evidence that calcium carbonate in the wet season after solubilised it can migrates, and after drier soil condition it typically deposit over pore walls. This leads to formation and stabilization of new macropores. Andic properties can occur in volcanic and non-volcanic environment in soils having a high content of low order clay minerals and Al-humus complexes, respectively. They induce in turn low bulk density, high specific surface, high water retention and high hydraulic conductivity. We firstly showed the distinctive hydraulic properties, namely soil water retention and hydraulic conductivity of some calcic and andic horizons measured applying the Wind's method. Then, we show how they deviate from an "average" expected behaviour (i.e. from comparison with the estimates applying several PTFs) for both the calcic and andic horizons. We performed a sensitivity analysis applying a physically based model in different upper boundary condition. Specifically, we tested the influence on the hydrological behaviour of (i) thickness and depth for the calcic soils and (ii) thickness and degree of andic properties in andic soils.

S08.01a -4

RESPONSE OF SATURATED HYDRAULIC CONDUCTIVITY (K_s) ON WATER TABLE ELEVATION IN A BOREAL ACID SULFATE SOIL

Virtanen Seija*^[1]

^[1]University of Helsinki ~ Department of Food and Environmental Sciences ~ Helsinki ~ Finland

Water table elevation is used for improving the quality of drainage waters from acid sulfate (AS) soils. We studied the effect of two water table management treatments on saturated hydraulic conductivity (K_s) of ripe and unripe horizons of an AS soil (Sulfic Cryaquept) using 10 semi-large undisturbed lysimeters in 2008-2010. The treatments were cropped high (HWC), cropped low (LWC) and bare high (HWC) water table. The plant cultivated was reed canary grass (*Phalaris Arundinacea*). The K_s of horizons (Ap, Bg2, Bgjc, BCg and Cg1) were determined by constant and falling head methods from undisturbed soil cores (c. 200 cm³) sampled from the field in the beginning (N=50) and respectively from the lysimeters in the end of the experiment (N=150). The K_s was log normally distributed. Comparisons were made by Mann-Whitney test. The K_s of HWC (Bg2 4.05 cmh⁻¹, Bgjc 6.37 cmh⁻¹, BCg 0.43 cmh⁻¹, medians) did not differ significantly from that of respective soil horizons in the field (Bg2 4.49 cmh⁻¹, Bgjc 7.40 cmh⁻¹, BCg 0.31 cmh⁻¹). Results support our hypothesis that the elevation of water table does not decrease K_s values of ripe AS soil horizons. The K_s of LWC (BCg 6.62 cmh⁻¹ and Cg1 3.22 cmh⁻¹) were higher than that of HWC and in the field (P<0.05). Drainage (LWC) increased K_s values both in ripe and unripe soil horizons in a short time period (<3 years). We conclude that the soil structure of a ripe AS soil is not easily destroyed by water table elevation.

PREFERENTIAL FLOW PATHS FORMATION AND INFLUENCE ON SOLUTE TRANSPORT IN AGRICULTURAL SOILS DEVELOPED ON GLACIAL TILL CLAYS

Gerke Kirill^[1], Shein Evgeny^[2], Korost Dmitry^[3]

^[1]Institute of Geospheres Dynamics ~ Geomechanics and Fluidodynamics Laboratory ~ Moscow ~ Russian Federation

^[2]Moscow State University ~ Soil Science Department ~ Moscow ~ Russian Federation ^[3]Moscow State University ~ Geology Department ~ Moscow ~ Russian Federation

Here we present some results of a case study in Vladimir region, Russian Federation. The main idea of a series of experiments (three in total) was to find any possible relationship between soil structure and transport properties. For that purpose 40-100 l of staining dye solutions were applied to soil areas of up to 1 m². After substantial infiltration soil blocks under application areas were vertically sliced every 10-20 cm to assess dye staining patterns. Each soil profile was carefully cleared and photographed using digital photo camera. During excavation undisturbed soil samples were taken from different stained and unstained portions of soil/genetic horizons. All samples were later processed in laboratory to assess standard hydro-physical properties (saturated hydraulic conductivity, water retention curve, etc.) and soil structure using X-ray microtomography with resolutions up to 2.5 μ m. All infiltration patterns were highly heterogeneous with pronounced preferential flow which mostly occurred via cracks in glacial till clay filled with sand. We report a definite difference in structure and permeability of such preferential flow paths. Finally, possible approach to account for these small inclusions in modeling is discussed.

INTERACTION BETWEEN SOIL WATER REPELLENCE AND VADOSE ZONE HYDROLOGY

Ritsema Coen J.*^[1], Oostindie Klaas^[1], Wesseling Jan^[1], Moore Demie^[1], Dekker Louis W.^[1]

^[1]Akterra - Wageningen University ~ Soil Science center ~ Wageningen ~ Netherlands

One of the least understood phenomena occurring in soils worldwide is the shift from a wettable to a water repellent state and vice versa, and the related effects on hydrology and ecosystem functioning. Not only information about weather conditions to trigger such shifts in soils is lacking, but the dynamic process of soil water repellence appearance and disappearance, including related effects on flow and transport remain largely unclear up to date. In this study, examples will be presented of the dynamic appearance and disappearance of water repellence in field soils. Regular measurements in fine grids reveal detailed information about spatial and temporal dynamics of soil water repellence in dependence of weather conditions. Soil water repellence can evolve rapidly during a time span of several distinct dry days, sometimes until depths of 30 cm or more. Rewetting of dry water repellent soil during wet periods appears to be a rather slow and difficult process. Evidence has been found that even after a long wet winter season, part of the soil profile still can remain water repellent. Occurrence of soil water repellence appears to regulate water infiltration and water distribution patterns in the root zone distinctly. Animations of soil water repellence development and simultaneous changes in water infiltration patterns will be presented. Soil water repellence relates to an extreme form of hysteresis in the soil water retention characteristics, and thus should be accounted for when simulating flow and transport in such soils.

To predict soil evolution induced by human activities at the century scale, we need to be able to model this evolution on such a time scale. For that purpose, coupled water-geochemistry modelling approaches are one possibility. If it is well recognized that soil hydraulic properties evolve in space, their temporal change are rarely taken into account. On the one hand, models hardly support the temporal variability of soil hydraulic properties that must be constant parameters all along the simulation and, on the other hand, the temporal evolution of soil hydraulic properties is often not known. Few experimental data concern the temporal variability of soil properties in the surface horizon at the annual scale, due to agricultural practices, for example. We propose here to investigate deeper horizons. We have performed an experiment to estimate the impact of sixteen years of subsurface drainage on the hydraulic properties of an Albeluvisol. We have focused our analysis on the heterogeneous E&Bt horizon, composed by two elementary pedological volumes (EPV) organised in a complex 3D structure. The analysis of serial sections demonstrated that the proportion and spatial arrangement of the EPVs evolved with time. Based on 3D reconstructions of the structure of the two EPVs and on the knowledge of their hydraulic properties, we have quantified the evolution of the hydraulic properties at the horizon scale, by using a 3D water transfer model. An application of this work will consist in including the temporal evolution of soil hydraulic into a model of soil evolution.

CHARACTERISATION AND CLASSIFICATION OF HYDROLOGICAL SOILSCAPES OF SOUTH AFRICA

Le Roux Pieter^[1], Hensley Malcolm^[1], Van Tol Johan^[1], Lorentz Simon^[2]

^[1]University of the Free State ~ Soil, Crop and Climate Sciences ~ Bloemfontein ~ South Africa ^[2]University of KwaZulu-Natal ~ School of Bioresources Engineering and Environmental Hydrology ~ Pietermaritzburg ~ South Africa

Water distribution in the landscape is uneven ranging from freely drained upland, recharge, oxidised, acidic soils; periodically saturated midslope, interflow, redox, variable acid soils and waterlogged wetland, saturation excess responsive, reduced, less acidic soils. These soils are topographically linked in a hydrological soilscape defined as hydrosequence, catena, toposequence, etc. The difference in soil water regimes can be explained by the interaction between the upper and lower vadose zones. The systematic redistribution system implies that systematic hillslope mechanisms (factors) are controlling processes (flowpaths and storage mechanisms) which leave signatures (soil properties) of hydrological activity. Soilscapes (48) on varying geology and in climates varying from arid to sub-humid were surveyed as part of several projects. Soil properties (chemical, water regime and drainage) indicative of control mechanisms, flowpaths and storage mechanisms correlated well with soil and terrain morphology. Conceptual soilscape hydrological response models were developed, characterised and classified according to their measured and inferred hydrological characteristics. The soilscapes are hydrologically grouped as i) soil flow dominant, ii) fractured rock flow dominant and iii) interactive soil/fractured rock flow typical. Conceptually group i) soilscapes contributes largely to hydrograph shoulder flow, group ii) more to hydrograph baseflow and group iii) to shoulder and to baseflow. Hydrograph correlation with changes in soil water contents in different soil types confirm these concepts.

SOIL-LANDSCAPES AND RISKS OF NUTRIENT LOSS TO WATER IN SIX IRISH AGRICULTURAL CATCHMENTS

Murphy Paul^[1], Wall David^[2], Melland Alice^[1], Mellander Per-Erik^[1], Shortle Ger^[1], Jordan Phil^[1]

^[1]Teagasc ~ Agricultural Catchments Programme ~ Wexford ~ Ireland ^[2]Teagasc ~ Environment, Soils and Land Use ~ Wexford ~ Ireland

Soils and soil management play a key role in determining hydrologic pathways and risks of nutrient (N, P) loss from soils in water. In particular, soil properties related to soil hydrology influence the partitioning of water between overland flow and subsurface flow and soil management influences the availability of nutrients for mobilization in water. Topography also interacts with soils, both in terms of topographic controls on pedogenesis and also as the key driver of hydrologic flow, to influence soil hydrologic pathways. These factors influence both the form and magnitude of nutrients mobilized and transported from soils in water. In addition, the spatial heterogeneity in soil properties and topographic factors and spatiotemporal heterogeneity in soil management within a catchment are critical in determining risks of nutrient loss to water. The Agricultural Catchments Programme is monitoring soils, soil management, nutrient loss pathways and nutrient stream export in six instrumented Irish agricultural catchments with contrasting soils and soil management characteristics (farming systems). This paper categorizes the catchments into soil-landscapes with a characteristic soil hydrologic functioning and associated hydrologic nutrient loss risk. Soil management and nutrient status are then used to characterise nutrient source risk. Spatial and temporal data on soil properties, topography, soil management and soil nutrient status within the catchments are presented. Risks of nutrient loss between catchments are compared in terms of the form, pathway and magnitude of nutrient loss. A preliminary verification of the assessed nutrient loss risk is made by comparison with measured nutrient stream exports for each catchment.

**HYDROLOGICAL PROPERTIES OF FOREST SOILS IN KARST ENVIRONMENTS:
PEDOTRANSFER FUNCTIONS FOR FOLIC HISTOSOLS, RENDZIC LEPTOSOLS AND
CHROMIC CAMBISOLS**

Delaney Christina M.^{*[1]}, Katzensteiner Klaus^[1], Schume Helmut^[1]

^[1]University of Natural Resources and Life Sciences Vienna ~ Department of Forest and Soil Sciences, Institute of Forest Ecology ~ Vienna ~ Austria

To expand current knowledge regarding unique hydrological properties of forest soils in karst environments; characterised as highly aggregated, shallow, with high organic matter and/or stone contents, including organic layers; Follic Histosols, Rendzic Leptosols and Chromic Cambisols have been investigated to develop and validate pedotransfer functions. Few pedotransfer functions currently exist which are applicable to forest soils with calcareous parent material and organic layers. The presented pedotransfer functions are based on physical and hydrological properties that have been empirically measured, including: bulk density and water content-matrix potential relations (pF-curves) as dependent variables; as well as morphological characteristics, particle size distribution, clay mineralogy, and organic carbon content as independent variables. Samples were gathered from representative forest sites in the Northern Limestone Alps based on a stratified sampling scheme, considering soil classification and forest stand composition. Linear models including regression analyses have been used to find relationships between the measured soil properties. Ultimately, functions were developed to combine results of these analyses to compute soil parameters, including hydraulic conductivity, based on limited available data. The calculated hydraulic conductivity values were validated with measurements from selected horizons. These pedotransfer functions have been developed with support from the European Regional Development Fund and national sources for application in hydrological modelling approaches to determine leaf area carrying capacities, quantify the effects of forest disturbance on soil water storage capacity and predicting regeneration of forest sites in the Northern Limestone Alps, Austria.

We have studied soils found in karstic landscapes of Yucatán in order to establish differences in pedogenetic pathways to give: Rendzinas, Terra Rossa and pedosediments in karstic pockets. At first glance, Rendzinas represent the less developed soils. However, they are structured, contain high percentages of clay, and show strong weathering. Terra Rossae are clayey, with high percentages of Fe and also strongly weathered. Karstic sinkholes have several sizes and morphologies. The smaller are infilled by pedosediments similar to Rendzinas, while the bigger ones contain materials which properties resemble Terra Rossae. First question to solve is how limestones, which are mostly compound of carbonates (>95%), can produce soils with high contents of clay, free of lime and strong weathered. We have compared the mineralogical and geochemical composition of several materials as possible sources of the parent material: limestone insoluble residue, volcanic materials from the neighboring areas, dust from Sahara and plutonic and metamorphic complexes from south Mexico. Results show a mixture of sources; however in situ strong weathering, under tropical climate, transform profoundly these materials. Second, Redzinas are shallow but not immature soils. What we propose is that Rendzinas are formed from eroded and redeposited Terra Rossa. Rendzinas in the new surface have the contribution of organic materials and nutriments from the limestone, giving high physical and chemical properties for cultivation, especially important for ancient Mayas. Finally, pedosediments of karstic pockets evidence a dynamic phase of landscape development (probably human-induced).

S08.01b -6

GREEN WATER CREDITS: A PROMISING CONCEPT FOR HYDROPEDOLOGY

Sjef Kauffman^[1], Johannes Hunink^[2], Peter Droogers^[3], Van Lynden Godert^{*[1]}

^[1]ISRIC - World Soil Information ~ WUR-ESG ~ Wageningen ~ Netherlands ^[2]FutureWater ~ . ~ Wageningen ~ Netherlands ^[3]FutureWater ~ . ~ Wageningen ~ Netherlands

Soil and Water Conservation (SWC) practices to combat soil water erosion in rainfed agricultural land are nowadays well catalogued and extensively described in literature (a.o. World Overview of Conservation Approaches and Technologies). However, implementation has been poor in many areas. How to introduce proper soil and water management remains a major challenge. The Green Water Credits (GWC) concept focuses on water in the unsaturated zone of the soil aiming at increased infiltration and reduced evaporation through SWC practices. Depending on local conditions, this may result in more soil water available for crop transpiration thus biomass production, less erosion and at the same time enhanced percolation to the underlying aquifer leading to regulated river flow, beneficial for downstream water uses - hydropower, irrigation, urban water and natural ecosystems. Land users need investments to implement and maintain SWC practices. The proposed GWC scheme, to be financed by public and private downstream beneficiaries, aims to invest in SWC practices. The capacity and response of the soil and ground water buffer are key functional properties of the GWC concept. Therefore, hydropedology plays a crucial role in defining the potential advantages of introducing SWC practices by providing soil survey data for hydrological models that show where these management interventions within a given watershed are likely to be most effective. The procedure, including cost/benefit, institutional and financial analyses, will be demonstrated for the Upper Tana catchment in Kenya where a GWC scheme is being implemented.

Knowledge of hydraulic functions is required for soil water management, modeling of water and solute fluxes and for plant-physiological studies. Generally the time and cost consuming devices sand box, kaolin box and pressure plate extractor are applied for measurement of the water retention function. The unsaturated hydraulic conductivity function is measured with the multi-step outflow method. The evaporation method provides an effective alternative. The evaporation method is frequently used for the simultaneous determination of hydraulic functions of unsaturated soil samples, i.e., the water-retention curve and hydraulic conductivity function. All methodic variants of the evaporation method suffer from the limitation that the hydraulic functions can only be determined to a maximum mean tension of ~ 50 kPa. This is caused by the limited measurement range of the tensiometers of typically 80 kPa on the dry end. We present a new, cost- and time-saving approach which overcomes this restriction (EEM). Using cavitation tensiometers and the air-entry pressure of the tensiometer's porous ceramic cup as additional defined tension value allows the quantification of hydraulic functions up to close to the wilting point. The procedure is described, uncertainties are discussed and measured as well as simulated test results are presented for soil samples of various origins, different textures (sand, loam, silt, clay, and peat) and variable dry bulk density. The experimental setup followed the system HYPROP which is a commercial device (UMS GmbH Munich) with vertical aligned tensiometers that is optimized to perform evaporation measurements.

ACCOUNTING FOR MATRIX DEFORMATION IN DOUBLE-PERMEABILITY DESCRIPTIONS OF WATER FLOW IN SWELLING CLAY SOILS

Coppola Antonio*^[1], Gerke Horst^[2]

^[1]UNIVERSITY OF BASILICATA ~ DEPT FOR AGRICULTURAL AND FORESTRY SYSTEMS MANAGEMENT - DITEC ~ Potenza ~ Italy ^[2]Leibniz-Centre for Agricultural Landscape Research (ZALF) ~ Institute of Soil Landscape Research ~ Müncheberg ~ Germany

When modeling flow through fractured soils, the fracture fraction is frequently assumed to be constant over time. However, changing fracture abundance with time may be more realistic of field soil with swelling clay which induces changes of soil structure in the soil profile. In this study, a dual-permeability model is discussed that accounts for swelling and shrinking effects on macropore and matrix domain hydraulic properties only at a local scale. The model assumes that the matrix domain or soil aggregate swell-shrink dynamics affects volume changes in macro-porosity, while the overall porosity of the total soil, and hence the layer thickness, remains constant. The specific novel aspects are the inclusion of the shrinkage characteristics in the two domain model that leads to an additional constitutive relation making the volume fraction of the fracture domain a function of the pressure head. The shrink/swell dynamics is incorporated in a one-dimensional dual-permeability model, in which water flow in both domains is described with a coupled set of Richards' equations. This simplified approach allows dealing with an expansive soil matrix at the local scale that behaves globally as a macroscopically rigid soil. The model will be tested by describing effects of shrinkage on the hydraulic behaviour of a swelling clay soil.

^[2]Karlsruhe Institute of Technology ~ Competence Center for Material Moisture ~ Eggenstein-Leopoldshafen ~ Germany

^[3]Uppsala University ~ Division of Solid State Physics ~ Uppsala ~ Sweden

Water content determinations by static heating at 105°C for 24 h serve as reference. However, some soil components, i.e. clay minerals, bind substantial amounts of water strongly. Swellable clay minerals bind water in hydration shells of interlayer cations. Hence, static heating at 105°C may insufficiently remove bound water and the moisture of soils containing swellable clay minerals may be falsified. Precise water content values are prerequisite for numerous technical applications of clays. Agriculture and climate change models require correct soil moisture values to calculate irrigation requirements and climate forecasts. Three materials and methods were compared. Two swellable clays (bentonite, vermiculite) and one non-swellable clay (illitic clay) were analyzed with focus on bound water. Water contents were determined by static heating (24 h/105 °C), Simultaneous Thermal Analysis (STA) and dielectric spectroscopy using calibration functions after Topp et al., Roth et al. and the Complex Refractive Index Model. Dielectric measurements were implemented in mid (2.0E+08...1.1E+09 Hz) and low (1.0E-04...1.0E+06 Hz) frequency range. Prior to measurements the materials were equilibrated at 11% and 93% r.h.. The low frequency range could differentiate the varying moisture of all clays, whereas the mid frequency range could only display the moisture differences of the illite. For quantitative moisture determinations the low frequency range is at the moment still unsuitable, since further relaxation processes mask the bound water polarization. STA revealed the strong water content underestimation of vermiculites when determined by static heating. Dielectric spectroscopy at mid frequency range severely underestimated up to 20% the moisture of clays containing swellable clay minerals.

S08.02a -4

GHG EMISSIONS FROM PEAT SOIL IN LYSIMETERS WITH A FALLING AND RAISING WATER TABLE

Berglund Örjan*^[1], Berglund Kerstin^[1]

^[1]Swedish University of Agricultural Sciences ~ Soil and Water management ~ Uppsala ~ Sweden

A lysimeter method with undisturbed soil columns was used to investigate how the water table affects the greenhouse gas (GHG) emissions from cultivated peat soils. The study was carried out using an organic soil from Örke in Sweden. This is a typical cultivated fen peat with low pH and high organic matter content. The 50 cm high lysimeters were supplied with water from below until saturation and the water table was then lowered from the surface in 5 cm step down to 45 cm below surface and raised again back to the surface. CO₂, CH₄ and N₂O emissions from the lysimeters were measured at all water table levels and twice when the lysimeters were let to dry out even more. CO₂ emissions increased as soon as air entered the profile and reached a stable rate (602 mg m⁻² h⁻¹) when the water table level was 20 cm but decreased when the soil got too dry. N₂O emissions were low during the drainage phase but increased to 3 mg m⁻² h⁻¹ when the water table rose to the surface again. CH₄ emissions were very low or negative.

COUPLING HEAT, VAPOR AND LIQUID WATER TRANSPORT IN THE THREE-DIMENSIONAL CRITERIA 3D MODEL.

Bittelli Marco^{*[1]}, Antolini Gabriele^[2], Ventura Francesca^[1], Marletto Vittorio^[2], Tomei Fausto^[2]

^[1]University of Bologna ~ Agricultural Science ~ Bologna ~ Italy ^[2]Agenzia Regionale Prevenzione e Ambiente (ARPA) Emilia-Romagna ~ Servizio Idro-Meteo-Clima ~ Bologna ~ Italy

The quantification of soil evaporation near the soil surface is a key process in land-surface processes on local, regional and global scales. Questions remain about the correct computation of key variables such as the soil surface resistance or the soil surface temperature, and the relative importance of different variables involved in the heat transfer process, such as vapor diffusivity and thermal conductivity. Finally, these processes should be computed in a three dimensional domain, for applications where the lateral components of the fluxes are of interest, such as drip irrigation, energy dissipation of buried power lines, or water and heat transfer studies performed on slopes. This study was conducted to: (a) implement a fully coupled, three-dimensional, numerical model to solve the governing equations for liquid water, water vapor, and heat transport and (b) test the numerical model with detailed measurements of soil temperature, heat flux, water content, and soil evaporation. The code implements a non-isothermal solution of the vapor flux equation that accounts for the thermally driven water vapor transport and phase changes, as well as solutions of liquid water and heat transport. Two experiments were employed to test the model: (1) a soil evaporation study in southern California where evaporation, energy budget components, soil properties, and soil temperature were measured and (2) a soil water content and soil temperature study in a soil profile in northern Italy. The two sites were selected to test the model in different climatic and pedological conditions.

ENVIRONMENTAL IMPACT OF THREE FERTILIZER N SOURCES FOR POTATO PRODUCTION ON SANDY SOILS

Cambouris Athyna^[1], Bernie Zebarth^[2], Noura Ziadi^[1], Cynthia Grant^[3], Craig Drury^[4]

^[1]Agriculture and Agri-Food Canada ~ Research ~ Quebec ~ Canada ^[2]Agriculture and Agri-Food Canada ~ Research ~ Fredericton ~ Canada ^[3]Agriculture and Agri-Food Canada ~ Research ~ Brandon ~ Canada ^[4]Agriculture and Agri-Food Canada ~ Research ~ Harrow ~ Canada

Appropriate N fertilization is essential to optimize potato yield and minimize environmental N losses. This study evaluated the effect of N fertilization with three N sources on tuber yield and plant N uptake, and on the risk of nitrate leaching on three growing seasons. Risk of leaching was assessed using residual soil nitrate (RSN) and the soil solution nitrate (SWN) concentrations. Treatments were four N rates (60, 120, 200, and 280 kg N ha⁻¹) for each of three N sources [ammonium nitrate (AN), ammonium sulphate (AS) and a controlled-release N (CRN)] plus an unfertilized control. The SWN was sampled biweekly from planting to harvest (nine sampling periods per years) via suction lysimeters. Soil was sampled (0-0.9 m) to determine NO₃-N at planting, at harvest, and in next spring. Tuber yield increased with N rates up to 200 kg N ha⁻¹, but was not affected by N source. Plant N uptake was reduced under wet climatic conditions for AN and AS but not for CRN. Even though all CRN was applied at planting, SWN was lower for CRN than AN or AS on many sampling dates. The low RSN at harvest and in the next spring (6.5 and 9.9 kg NO₃-N ha⁻¹, respectively) demonstrates that most of our leaching occurred during the growing season. The CRN may be more advantageous in increasing plant N uptake and reducing the risk of early season leaching in sandy soils especially in a rainy growing season.

VEGETATION IMPACT ON THE HYDROLOGY OF AN AEOLIAN SANDY SOIL

Lichner Lubomir*^[1]

^[1]Institute of Hydrology, Slovak Academy of Sciences ~ Soil Hydrology ~ Bratislava ~ Slovakia

Vegetation impact on the hydrology of sandy soil was studied at four sites with different vegetation cover: (1) no vegetation ("Pure sand"), (2) biological soil crust (BSC), consisting of algae, fungi and mosses ("Glade soil"), (3) grass ("Grassland soil"), and (4) Scots pines ("Forest soil"). Three algal species were isolated from glade soil and grown in the laboratory on sterile pure sand as monoalgal and bialgal crusts. The persistence of water repellency was estimated using the WDPT test, the water S_w and ethanol S_e sorptivity, hydraulic conductivity k , index of water repellency R and water repellency cessation time t_c were estimated from the cumulative infiltration vs. time relationship obtained using a minidisk infiltrometer at $h = -2$ cm. The heterogeneity of water flow during dye tracer infiltration experiments was assessed using two parameters. Vegetation cover influenced the hydrophysical parameters and heterogeneity of water flow in sandy soil considerably. WDPT and R increased in the order: Pure sand < Glade soil < Grassland soil < Forest soil, and in pure sand they were more than 3000-times and 240-times smaller compared to forest soil, respectively. This was reflected in S_w and k , which had the opposite trend, and in forest soil were almost 170-times and 690-times smaller compared to pure sand, respectively. Despite the smaller impact on WDPT, the algal crusts had nearly the same impact on S_w and k of pure sand as the BSC at glade site. t_c increased with an increase in WDPT for all the dried algal crusts.

SOIL FUNCTIONING INDICATORS (INFOSOL): A METHODOLOGICAL APPROACH FOR DEVELOPING AND ASSESSING DYNAMIC SOIL FUNCTIONS WITHIN THE SOIL PROTECTION STRATEGY CONTEXT

Alonso Alice^{*[1]}, Charles Bielders^[1], Martin Germeau^[1], Mathieu Javaux^[1], Marnik Vanclooster^[1], Samuel Mattern^[1], Eric Laloy^[1], Christian Roisin^[2]

^[1]Université catholique de Louvain ~ ELle ~ Louvain-la-Neuve ~ Belgium ^[2]Centre wallon de Recherches agronomiques ~ Département Agriculture et Milieu naturel - Unité Fertilité des sols et Protection des eaux ~ Gembloux ~ Belgium

Soils are subjected to multiple pressures which cause their degradation and endanger their ecological, economic, social and cultural functioning. This justifies the development of indicators for driving sustainable soil management strategies and policies. In this context, numerous soil quality indicators are currently available that allow measuring the physical, chemical and biological status of soil. Yet, only few approaches are available for assessing the soil functioning. This study develops and evaluates indicators for the water flux regulation function of soil. The methodological approach encompasses three steps: (i) the definition and measurement of the relevant reference physical properties of the soil (basic indicators) allowing to assess the physical qualities relative to the environmental function mentioned above; (ii) the development and definition of a set of synthetic indicators of soil functioning, based on 2-dimensional simulation of water fluxes using Hydrus 2D/3D, which explicitly considers the soil structural heterogeneity generated by tillage; and (iii) the establishment of relations between the developed synthetic indicators of soil functioning and the more easily measurable basic indicators. We illustrate this approach for two different land cultivation strategies (ploughing and reduced tillage), two soil types (silt loam and sandy loam) and 2 levels of compaction due to traffic.

The aim is to demonstrate that soil has stored the information of flood events from former centuries and that soil information can be used to protect the current inhabitants from future flooding. Soil information is likely to become a more important tool in flood management and flood protection. Fluvisols are built up from many layers and have archived the sediments from previous flood periods in unique soil layers. These soil profiles were built up for several hundred and even thousands of years. Only during the last century dams against flooding were built and floods therefore became rare or “extreme” events. Then the flooding exceeds the height of the dam and despite the protective measures there will be huge damages and even threatening to human lives. Therefore in recent decades an increasing amount of flood forecast models were developed to cope with the risk for the concerned population. Here we present an alternative to flood forecast models based on analyzing soil profiles. This was demonstrated in Gars am Kamp, Lower Austria, at the flood event of 2002. The “forecasting ability” of soil profiles from Gars am Kamp was comparable to advanced flood risk models. In a current approach within the EU SONDAR (Soil awareness network in the Danube Region) project the trans-boundary Slovak Austrian region of Zahorska Ves/Angern and the river Morava is subject to detailed tests. Finally an outlook will be given on how this “SONDAR” method can be used at larger scales in the entire Danube River Basin.

The wet climate regions of the northwestern Iberian Peninsula have large areas of commercial plantations with eucalypt and maritime pines. Forestry practices may affect the soil water characteristics which regulate water balance, and therefore have impacts on plant-water availability, groundwater recharge and runoff. However, characterizing soil hydrological properties and estimating water balance in these forests poses several challenges, especially due to the distinct seasonality of rainfall and water availability and the strong soil water repellency in the dry season, which impacts infiltration and soil water behavior. Given the economic importance of forestry and the frequent occurrence of drought years, it is important to gain more understanding on the soil and water relations to support the sustainable management of forest stands. This work will present the results of a bilateral Portuguese-German project investigating soil and water interactions in eucalypt and pine stands in central Portugal. For both forest types water retention curves and unsaturated conductivities were analysed in the laboratory. In the field, the undisturbed infiltration capacities were measured quantitatively (disk and ring infiltrometers) and qualitatively (brilliant blue dye tracer) under repellent and non-repellent conditions. The temporal patterns of soil moisture, repellency and associated meteorological conditions were also measured during the hydrological year 2011/12. The results are expected to provide insights on the seasonal behavior of forest soils, the role of soil water repellency in this seasonality, and the mechanisms by which repellency influences infiltration rates and pathways. These insights will help improve water balance calculations for eucalypt and pine plantations.

SPATIAL VARIABILITY OF SOIL PHYSICAL PROPERTIES IN A CULTIVATED FIELD

Gülser Coskun^[1], Ekberli Imanverdi^[1], Candemir Feride^[1], Demir Zeynep^[1]

^[1]Ondokuz Mayıs University, Faculty of Agriculture ~ Soil Science and Plant Nutrition ~ Samsun ~ Turkey

*Prediction of soil physical properties is important for site specific management practices in precision agricultural systems. Generally, the aim of soil cultivation is to form a homogeneous media to supply optimum growth conditions for seeds and plants. In this study, spatial variability of some soil physical properties in a cultivated field such as; bulk density (BD), penetration resistance (PNT), saturated hydraulic conductivity (Ks), field capacity (FC) and permanent wilting point (PWP), were determined by geostatistical method. While BD values varied between 1.12 and 1.41 g cm⁻³, PNT resistance in 15 cm soil layer varied between 0.66 and 1.88 MPa. Also, Ks (1.46 to 3.37 mm h⁻¹), FC (30.40 to 39.66%) and PWP (19.22 to 24.42%) values showed variations among the soil samples. In kriging interpolation for the spatial variability of soil physical properties, the biggest r² and cross validation r² values were determined with spherical model for BD, PNT, Ks, FC values, and exponential model for PWP values. Spatial dependences of the physical properties were found to be strong in the field. The semivariograms for BD, PNT, Ks, FC and PWP showed spatial dependences with the ranges of 12.75, 12.17, 12.82, 10.24 and 112.23 m, respectively. While PNT values significantly increased with increasing BD (0.366**) and decreasing moisture content (-0.408**), Ks values significantly increased with increasing BD (0.340*), and decreasing clay content (-0.905**) and PNT (-0.288*) values in the field.*

APPLYING PEDOTRANSFERFUNCTIONS: THE SORCERER'S APPRENTICE AT WORK?

Bouma Johan*^[1]

^[1]formerly Wageningen University ~ soils ~ Wageningen ~ Netherlands

J. Bouma, em.prof. soil science, Wageningen University, The Netherlands Pedotransferfunctions (PDF) use easily available soil survey (pedological) data to predict complex physical and – chemical soil characteristics that are difficult and expensive to measure. Examples are e.g. texture, bulk density and %C to predict by regression analysis hydraulic conductivity and moisture retention and the phosphate adsorption capacity by regressing the Fe and Al content. Two types were initially distinguished: continuous and class PDF's. Continuous PDF's provide poor results when: (i) based on poor measurements of both the complex soil characteristics and the pedological data; (ii) applied beyond the range of measured data on which PDF's were based; (iii) used for applications for which they are not suitable. An example is K_{sat} , which cannot be estimated by PDF's, and (iv) no attention is paid to the soil series from which PDF's are derived because use for quite different soil series may be problematic. We suggest more attention for class PDF's, such as, for example, hydraulic conductivity and moisture retention curves for certain pedogenic soil horizons in a given soil series. This also allows expressions for spatial variability, useful for e.g. Monte Carlo simulations. In conclusion, PDF's can be a "pleasant reality" when they are not used by sorcerer apprentices who know how to start but not how to stop.

SOIL INFERENCE SYSTEMS: MAKING THE MYTH INTO A REALITY

Morris Jason^{*[1]}, Mcbratney Alex^[1], Minasny Budiman^[1]

^[1]The University of Sydney ~ Faculty of Agriculture, Food & Natural Resources ~ Sydney ~ Australia

The soil inference system was proposed in 2002 by the authors as a way of collecting and making better use of pedotransfer functions that have been abundantly generated. The idea is to generate an expert system that will predict various soil properties with their confidence of prediction given a limited amount of input data. The inference system makes use of PTFs as its knowledge-base. The initial proof-of-concept was made using a simple MS Excel spreadsheet. A proper SINFERS prototype was then developed by Tranter and Morris in 2008 using a rule engine to match facts containing known soil property data with rules that “know about” using pedotransfer functions (PTFs). SINFERS uses these rules to select appropriate PTFs, then it computes new property values and error estimates, and then it reasserts those computed property values as new facts. This causes more matching patterns and more PTFs to fire cyclically until the knowledge base is exhausted and SINFERS has inferred everything it can about what it was originally given. To-date, there have been no research applications that do what SINFERS aims to do. There have been some attempts at pattern matching using nearest-neighbour algorithms and neural nets. Significant research has been done to establish the validity of pedotransfer methods and their application to multiple domains. In this paper, we will demonstrate the realization of SINFERS implemented in the Java expert System Shell (Jess).

S08.03 -3

HOW ACCURATE AND RELIABLE ARE PAN-EUROPEAN PEDOTRANSFER FUNCTIONS?

Weynants Mélanie^[1], Tóth Gergely^[1], De Brogniez Delphine^[1]

^[1]European Commission Joint Research Centre ~ Land Management and Natural Hazards Unit ~ Ispra ~ Italy

Availability of soil hydraulic properties at the European scale provides input data for hydrological modelling. HYPRES database was created to develop pedotransfer functions (PTF) for Europe, based on FAO texture classes (class PTF) or on continuous clay, silt, organic matter contents and bulk density (continuous PTF). The objective of this study was to compare the hydraulic properties obtained with the two methods in terms of expected accuracy and geographical reliability. The class PTF were applied on the Soil Geographical Database of Europe (SGDBE) and on LUCAS-soil database. The continuous PTF were applied on LUCAS-soil database. Our results showed that differences between both datasets were larger when using different PTF. Using the class PTF, differences occurred when comparing point data (LUCAS-soil) with the dominant and the subdominant soil typological units of SGDBE. Differences were larger in geographic areas where there are fewer HYPRES training data. This showed that the use of continuous PTF allows for more variability in the results and that the reliability of HYPRES PTF is spatially very variable. We therefore suggest to create a second version of HYPRES, filling in the gaps of the first version.

THE ROLE OF PEDOTRANSFER FUNCTIONS IN THE UNCERTAINTY AND SENSITIVITY ANALYSIS OF SIMULATED SOIL MOISTURE

Loosvelt Lien^[4], Vernieuwe Hilde^[2], Pauwels Valentijn^[4], Cornelis Wim^[3], De Lannoy Gabrielle^[4], De Baets Bernard^[2], Verhoest Niko^[4]

^[1]Ghent University ~ Water and Forest Management ~ Ghent ~ Belgium ^[2]Ghent University ~ Department of Mathematical Modelling, Statistics and Bioinformatics ~ Ghent ~ Belgium ^[3]Ghent University ~ Department of Soil Management ~ Ghent ~ Belgium ^[4]Ghent University ~ Department of Water and Forest Management ~ Ghent ~ Belgium

For simulations in basins where soil information is limited to soil type maps, modellers are forced to rely on pedotransfer functions (PTFs) to estimate the soil hydraulic parameters (SHPs). However, PTFs are often applied outside the geographic region for which the PTF was originally developed. In this presentation, it is shown that the geographic origin of the PTF (region specific versus non-region specific) plays a crucial role (i) in assessing the uncertainty on the simulated soil moisture, arising from within-class-variability of the soil hydraulic parameters, and (ii) in quantifying the sensitivity of the simulated soil moisture to changes in soil texture composition. Continuous PTFs are applied to 3200 texture samples distributed over the entire textural triangle to construct discrete probability distributions of the SHPs for each individual USDA soil class. The parameter distributions are propagated through a hydrologic model to result in a discrete probability distribution of the simulated soil moisture content. Results show that both the range and the shape of the probability distributions are highly affected by the geographic origin of the PTFs. Furthermore, the continuous PTFs are incorporated in a sensitivity analysis to determine the effect on simulated soil moisture by perturbing the soil texture composition. We present a methodology to make sensitivity indices suitable for the compositional nature of soil textural information. Based on the calculated sensitivity index, zones of high and low sensitivity are indicated on the texture triangle.

S08.03 -5

APPLICATION OF PEDOTRANSFER FUNCTIONS FOR 3D-DISTRIBUTED HYDRAULIC PROPERTIES OF GENERATED CATCHMENT MODELS

Bartsch Robert^[1], Maurer Thomas^[1], Schneider Anna^[2], Gerke Horst H.*^[4]

^[1]Brandenburg University of Technology ~ Research Center Landscape Development and Mining Landscapes ~ Cottbus ~ Germany ^[2]Brandenburg University of Technology ~ Chair Geopedology and Landscape Development ~ Cottbus ~ Germany ^[3]Leibniz-Center for Agricultural Landscape and Landscape Development ~ Institute for Soil Landscape Development ~ Muencheberg ~ Germany ^[4]Leibniz Centre for Agricultural Landscape Research (ZALF) ~ Institute of Soil Landscape Research ~ Muencheberg ~ Germany

Knowledge of the spatial distribution of hydraulic properties is essential for the assessment of water flow and hydrological catchment models. In artificially-created catchments, sediment distributions are determined by the technological processes, which provide the initial spatial distributions of hydraulic properties. The question was how the 3D-distributed model of catchment structures and spatial sediment patterns could be transformed into an 3D-distributed model of the hydraulic properties that can be used to run hydrological catchment modeling. We compared pedotransfer functions for application to initial soils of an artificially-constructed hydrological catchment located near Cottbus, Germany. The aim was to evaluate the functions and analyze the impact of generated sediment distributions on the distribution of hydraulic parameters in the catchment. Three pedotransfer functions were tested: (i) Arya and Paris (1981), (ii) Vereecken et al. (1989) and (iii) Vereecken et al. (1990). The functions were applied to different realizations of spatial sediment and structure distributions, and were evaluated by determining hydraulic properties from a lower resolution sediment spatial distribution with those obtained from a higher resolution spatial model. Hydraulically different regions were obtained by integration and upscaling. The angle of the basic grid cell hydraulic structures were included into the upscaled regions to account for hydraulic anisotropy in the spatial model. These approaches will help improving the understanding of effects of small-scale sediment structures on hydraulic properties in initial soils. This example also helps understanding the effect of sediment structures on hydraulic properties in initial soils of typical reclaimed mine spoil sites.

INFLUENCE OF PARTICLE-SIZE DISTRIBUTION MEASUREMENT METHOD ON THE PREDICTION OF SOIL WATER RETENTION CURVE

Antinoro Chiara^[1], Bagarello Vincenzo^[1], Ferro Vito^[1], Giordano Giuseppe^[1], Iovino Massimo^{*[1]}

^[1]Università degli Studi di Palermo ~ Dipartimento dei Sistemi Agro-Ambientali ~ Palermo ~ Italy

Application of the Arya and Paris (AP) model to estimate the soil water retention curve requires detailed particle-size distributions (PSD) that can be obtained by fitting a continuous model to traditional sieve-hydrometer (SH) data or using the laser diffraction (LD) method. The AP model was applied to 40 Sicilian soils for which PSD was measured by both SH and LD methods. The scale factor alpha was set equal to 1.38 (procedure AP1) or estimated by a logistic model with parameters gathered from literature (procedure AP2). To simplify application of the AP model, a relationship for estimating a soil-specific alpha value from clay content was developed (procedure OPT). For both SH and LD data, procedure AP2 allowed a more accurate prediction of the water retention than procedure AP1 confirming that a unique value of alpha for soils very different in texture is not suggested. Discrepancies in estimated water retention curves were attributed to underestimation of PSD by the LD method for the finer particle diameters. Overall, SH data resulted in more accurate predictions of the water retention curve than LD data. From comparison of alpha-distributions it was supposed that the PSDs determined by the traditional sieve-hydrometer method are in more close similarity with the measured water retention curve than those determined by the LD method. For a validation dataset of 170 Sicilian soils, the most accurate predictions of the water retention curve were obtained by procedure OPT that can be considered a valid alternative to the more complex logistic model.

S08.03 -7

PEDOTRANSFER FUNCTION BASED MULTI-MODEL ENSEMBLE ESTIMATION OF SOIL WATER STORAGE, DRAINAGE AND ACTUAL EVAPOTRANSPIRATION

Diederik Jacques*^[1]

^[1]Belgian Nuclear Research Centre ~ Performance Assessment ~ Mol ~ Belgium

Estimation of soil water fluxes and water storage is a key parameter for different applications. However, exact soil hydraulic parameters are often missing. Basic soil properties might be available which allows for estimating soil hydraulic parameters using pedotransfer functions (PTF). To assess the uncertainty associated with the use of PTFs, ensemble predictions with multiple PTFs (multi-model predictions) are carried out resulting in an ensemble (i.e. statistical) estimate of the variable of interest. In this study, ensemble estimates of the actual evapotranspiration, drainage and water storage are obtained based on 27 PTFs. The analysis is done for soil profiles in different textural classes and a 37-year long record of daily values of meteorological data for the Campine region in Belgium. Statistics are analyzed at different temporal scales (daily, seasonally, and annually). The variability among the estimated hydraulic properties is large between the different estimates within one textural class. Consequently, the difference between the minimum and maximum values within a textural class was large. On the other hand, for the yearly drainage and actual evapotranspiration, the interquantile range was small. Therefore, the medium of the 27 simulations can be taken as an estimate of the yearly drainage and actual evapotranspiration. The approach is also used to characterize the variability between year and within years (between the PTF) and can thus be used to define the uncertainty in the drainage, the actual evapotranspiration and the water storage.

WHY DO THEY KEEP REJECTING MY MANUSCRIPT - DO-S, DON'T-S AND NEW HORIZONS OF PTF STUDIES

Nemes Attila*^[1]

^[1]University of Maryland ~ Plant Science and Landscape Architecture ~ College Park ~ United States

In recent years, a score of manuscripts have been – and keep being - submitted to soils journals of international interest on the general topic of developing pedotransfer functions (PTFs). Many of them are returned to the authors, not being accepted, and many of those manuscripts get resubmitted to other journals without substantial changes – and without success. This presentation is based on the opinion and insights of a number of scientists experienced in writing, reviewing, editing and/or advising pedotransfer related papers, and gives advice on how to make PTF-related research efforts more fruitful for authors and more interesting and useful to the general readership.

EVALUATING THE WATER CONTENT MATRIC POTENTIAL RELATIONSHIP OBTAINED FROM MULTI STEP OUTFLOW EXPERIMENTS WITH HIGH RESOLUTION GAMMA DENSIMETRY

Lennartz Franz^{*[1]}, Andre Bieberle^[2], Mario Wanski^[1], Yvonne Diesner^[1]

^[1]University of Technology, Dresden (TUD) ~ Institut of Hydrology and Meteorology (IHM) ~ Dresden ~ Germany

^[2]Helmholz-Zentrum Dresden-Rossendorf ~ Institut für Sicherheitsforschung / Abteilung Experimentelle Thermo-fluiddynamik ~ Dresden ~ Germany

Dynamic Multi Step Outflow (MSO) experiments serve for the estimation of the parameters from soil hydraulic functions like e.g. the Mualem/ van Genuchten model. The soil hydraulic parameters are derived from outflow records and corresponding matric potential measurements from commonly a single tensiometer using inverse modeling techniques. We modified the experimental set up allowing for the simultaneous measurement of the matric potential with three tensiometers and the water content using high resolution gamma densimetry (Bieberle 2008). The soil hydraulic parameters were derived using the data of the tensiometer in the middle of the sample together with the outflow record. The HYDRUS 1D model with these parameters then allowed for the simulation of the MSO experiments. Subsequently we compared the matric potential and water content measurements at different levels of the soil samples with the values derived from the model simulations. While the measurements and the model results were overall in good agreement for the location of the tensiometer that was used within the inverse parameter estimation, we obtained partly significantly deviating results for the other tensiometer positions and thus, different water content matric potential relationships at different levels of the sample. The highest deviations were achieved at the levels with the highest flow dynamics. Considering the soil samples as homogenous we concluded that non equilibrium flow during the dynamic outflow experiments is the major cause for the observed results.

NUMERICAL DETERMINATION OF EFFECTIVE HYDRODYNAMIC PROPERTIES FOR AN HETEROGENEOUS SOIL

Rossa Virginie^[1], Stéphane Ruy^[2], Hervé Bolvin^[1], Samuel Buis^[2], Gaelle Lefeuvre-Mesgouez^[1], Arnaud Mesgouez^[1]

^[1]Université d'Avignon et des Pays du Vaucluse-INRA ~ UMR EMMAH Environnement Méditerranéen et Modélisation des Agro-Hydrosystèmes, Département Physique ~ Avignon ~ France ^[2]INRA ~ UMR EMMAH Environnement Méditerranéen et Modélisation des Agro-Hydrosystèmes ~ Avignon ~ France

Working out scenarios of sustainable use of groundwater resources in a global climate change context involves the development of continuum surface-soil-groundwater models in agro-ecosystems. These models require an effective parameter set at unit cell scale, typically an agricultural field, which takes into account ground heterogeneities at smaller scale. Characterizing these heterogeneities represents an issue since they depend mainly on the spatial soil structure variability and the constitutive material properties. We propose a two scale approach in order to numerically estimate the recharge draining to groundwater. Soil properties are those of an agricultural stony soil in La Crau area (South of France) where an intensive irrigation is applied. At local scale (m^2), a numerical methodology is proposed to determine hydrodynamic behavior for highly heterogeneous stony soils. The purposes consist in identifying and studying the sensitivity of effective parameters. Digital samples mixing fine soil and stones are generated. Effective parameters, particularly the retention and hydraulic conductivity curves, are determined with numerical simulations based on the use of a C++ object oriented programming software named FAFEMO. The sensitivity analysis is performed by numerous simulations with various material proportions, and according to the spatial organization (following a vertical gradient of distribution) and the hydrodynamic properties. At global scale (ha), the overall field response by stochastic modeling and spatialization of effective parameters is defined. The presentation proposed here concerns the first point.

S08.04a -3

REVIEW ON NON-EQUILIBRIUM WATER FLOW IN SOIL

Durner Wolfgang^[1], Efstathios Diamantopoulos^[1]

^[1]TU Braunschweig ~ Soil Physics ~ Braunschweig ~ Germany

Water flow in unsaturated soils is frequently not following the process assumption of a local equilibrium between water content and matric potential, and thus cannot be described by the standard Richards equation with time-invariant hydraulic properties. With the generic term "dynamic non-equilibrium", a wide variety of phenomena that are acting on different time and length scales is encompassed, e.g., water-air interface dynamics on a pore-scale, effects of partial and time variable water repellency, effects caused by restricted air permeability, or effects associated with local soil heterogeneity. This contribution gives an overview on the various phenomena that cause "dynamic non-equilibrium" of water flow in soils. Starting from historic and recent measurements of flow experiments on the macro scale, current perceptions and effective modeling approaches will be discussed. We conclude that there is an urgent need for precision measurements that are designed to quantify dynamic effects, in order to improve understanding and modeling of these phenomena, and also in order to assess their importance for field scale water flow.

EFFECT OF NON-EQUILIBRIUM SOLID SURFACE WETTING PROPERTIES ON TIME-DEPENDENT CAPILLARY RISE

Reszkowska Agnieszka^{*[1]}, Bachmann Jörg^[1], Diamantopoulos Stathis^[2], Durner Wolfgang^[2]

^[1]Leibniz University Hannover ~ Institute of Soil Science ~ Hannover ~ Germany ^[2]Technische Universität Braunschweig ~ Institute of Geoecology ~ Braunschweig ~ Germany

Capillary rise of water is a well known phenomenon where water moves against gravity until reaching a hydraulic equilibrium. Until now, not only hydraulic but also solid surface wetting equilibrium has been assumed. However, our investigations showed that in some cases water can interact with the surface functional groups leading to decline in local contact angles and, as a consequence, increase in the height of the capillary rise. In our studies we used disturbed, sandy soil samples taken from the Fuhrberg in Germany from two sites: forest and field; and two soil layers: topsoil (forest and field) and subsoil (field). The samples were air-dried, homogenized, dried to different temperatures (50, 60, 90°C), and packed to PVC columns (50 cm height). Afterwards a capillary rise experiment was performed for different periods of time. The results showed that with time the capillary rise increased over months for the soils taken from the topsoil while there was no time effect for samples taken from the subsoil. In the wetted part of the column, we measured always hydraulic equilibrium with respect to the supply water level. Nevertheless, even during hydraulic equilibrium we observed an increase of the water content with time. These results indicate that in case of unstable surface conditions (topsoil) the functional groups of soil can rearrange in contact with water leading to changes in hydraulic soil properties while in case of stable surface conditions the surface of soil remains unchangeable and the hydraulic properties do not vary.

DYNAMIC NON-EQUILIBRIUM EFFECTS IN SOIL HYDRAULIC PROPERTIES ESTIMATED WITH THE EVAPORATION METHOD: EXPERIMENTAL AND MODELING APPROACH

Diamantopoulos Efstathios^[1], Durner Wolfgang^[1]

^[1]Technische Universität Braunschweig ~ Institut für Geoökologie ~ Braunschweig ~ Germany

The knowledge of soil hydraulic properties is fundamental to characterizing water retention and flow in soils for many soil hydrologic applications. The traditional approach for modeling soil water dynamics is to use the soil hydraulic properties estimated under static methods. However, experimental observations have shown that the soil hydraulic properties estimated under static and dynamic methods can differ substantially. These observations are often described by the term “dynamic non-equilibrium” or “dynamic effects”. To investigate the occurrence and extent of dynamic effects in transient flow experiments, we conducted evaporation experiments with flow interruptions. In the evaporation experiments, non-equilibrium effects appear as a relaxation of the pressure head over time, while the macroscopic water content distribution appears static. We developed a simple non-equilibrium model to quantitatively describe the observations. The model considers two continua at the macroscopic scale: one continuum is described by the Richards equation and the second, associated with non-equilibrium water flow, is described by an extended Richards equation using the Ross and Smettem non-equilibrium approach. This model can describe the dynamic effects occurring in our evaporation experiments very well.

Water infiltration into heterogeneous, structured soil leads to hydraulic non-equilibrium across the infiltration front. That is, the water content and water potential are not in equilibrium according to some static water retention curve. The water content increases more rapidly in more conductive regions followed by a slow relaxation towards an equilibrium state behind the front. An extreme case is preferential infiltration into macropores. The aim of our study is to develop an upscaled description of water dynamics which conserves the macroscopic effects of non-equilibrium and which can be directly linked to structural properties of the material. A critical question is how to define averaged state variables at the larger scale. We propose a novel approach based on flux-weighted averaging of hydraulic potential, and compare its performance to alternative methods for averaging. Further, we suggest some meaningful indicators of hydraulic non-equilibrium that can be related to morphological characteristics of infiltration fronts in quantitative terms. These methods provide a sound basis to assess the impact of structural connectivity on hydraulic non-equilibrium. We demonstrate our approach using numerical case studies for infiltration into two-dimensional heterogeneous media using three different structure models with distinct differences in connectivity. Our results indicate that an increased isotropic, short-range connectivity reduces non-equilibrium, whereas anisotropic structures enforce it. We observe a good agreement between front morphology and upscaled non-equilibrium. Thus, the new approach may help to better represent hydraulic non-equilibrium including preferential flow in models based on Richards equation.

STUDY OF MACROPORE FLOW USING ELECTRICAL RESISTIVITY TOMOGRAPHY?

Noell Ursula^{*[1]}, Ganz Christina^[2], Lamparter Axel^[1], Wießner Claudia^[1]

^[2]Leibniz University ~ Soil Science ~ Hannover ~ Germany ^[1]Federal Institute for Geosciences and Natural Resources ~ Groundwater and Soil ~ Hannover ~ Germany

Water flow in unsaturated soil can relatively easily be observed using time lapse high resolution electrical resistivity tomography (ERT). However, in order to conclude from the inversion results the “true” process critical questions with regard to resolution, inversion bias and non unique relationships between water content and resistivity need to be answered. There can be no general answers because i.e. resolution depends on the resistivity, its absolute values, contrasts and heterogeneity. In order to study those critical questions in 2011 two different experiments were carried out on a Loess soil close to Hannover, Germany. Firstly, a ponded infiltration experiment and secondly an irrigation experiment both using water coloured with brilliant blue. Before, during, and after both experiments ERT array measurements were conducted. After the experiments the areas were excavated, undisturbed soil samples (soil cores) were taken, water content and matric potential was measured. From the ponded infiltration experiment where within 25 min 30 l water infiltrated in a circular area of 40cm diameter (716mm/h) it became clear that macropore flow is of major significance at this site. The ERT inversion revealed indeed hints for this rather quick process. Contrary to the irrigation experiment (4.2 mm h⁻¹ for 48h) and greatly different to the experiments in sand the inversion showed narrow infiltration paths for a short time. Three different time lapse inversion strategies were tested and showed significant differences. After the calculation of the time correction the process could be reconstructed with higher reliability.

THE PROCESS OF IN SITU WATER INFILTRATION IN STRUCTURED AND NON-STRUCTURED FIELD SOILS: COMPLEMENTARY ANALYSIS OF GEOPHYSICAL ERT DETECTION AND SOIL HYDRAULIC MEASUREMENTS

Ganz Christina^{*[1]}, Ursula Noell^[2], Bachmann Jörg^[1], Axel Lamparter^[2], Wilhelmus H.m. Duijnisveld^[2]

^[1]Leibniz Universität Hannover ~ Institut für Bodenkunde ~ Hannover ~ Germany ^[2]Bundesanstalt für Geowissenschaften und Rohstoffe ~ Bodengeophysik ~ Hannover ~ Germany

To assess the specific transport dynamics of water under different boundary conditions it is crucial to detect the process in situ with dynamically operating sensors. Measuring the state variables with TDR and tensiometers is a common procedure, but only punctual information from a few locations about their time-dependency can be obtained. Therefore, time-lapse Electrical Resistivity Tomography measurements are simultaneously conducted together with measurements of matric potential and water content. Ponded infiltration and irrigation experiments were carried out with dyed water (Brilliant Blue) on a poorly structured sandy soil and on a structured loess soil. Data were recorded using the ERT, TDR and tensiometer techniques. In the sandy soil, infiltration characteristics are defined by saturation and pressure overshoot caused by water repellency. The specific shape of the infiltrating water plume can be reproduced by the ERT results, but there is still a discrepancy between resolving the anomalous saturation distribution during the infiltration due to the uncertain relationship between resistivity and water content. In the loess soil simultaneous macropore and matric flow under saturated flow conditions under ponding occur, whereas during the irrigation experiment only matric flow is observed. We conclude from our results that combining non-destructive geophysical and soil hydraulic sensors helps significantly to describe the observed phenomena and the simultaneously measured parameters can together be used improving the ERT inversion and the hydraulic modeling.

Preferential flow in unsaturated soils may due to local heterogeneities like worm burrows but also to front instability leading to unstable finger flow (fingered pattern) in sandy textured soils. This last spontaneous preferential flow cannot be described by the standard Richards equation. Cueto-Felgueroso and Juanes proposed recently a phase field model in order to take into account a macroscopic surface tension effect at the front [1]. The validity domain of this model is poorly known as is the link between the equation parameters and the soil characteristics. This presentation aims at answering these questions using simulations and experiments. The governing equation is analogous to the lubrication equation for which we pointed out the numerical difficulties due to the fourth order term. A numerical code to perform time integration and bifurcation analysis was developed in [2] allowing to determine the onset of instability and its resulting dynamics in the parameter space [3]. We apply these numerical tools to stratified media problems, like sand layers with different granulometries. Instability onset and flow pattern are obtained in a wide parameter domain. Additionally, we perform experiments using, for instance, X-ray tomography allowing to track in space and in time the development of fingered flows [4]. [1] Cueto-Felgueroso and Juanes, Water Res. EVIDENCE FOR HYDRAULIC NON-EQUILIBRIUM AT THE AQUIFER SCALE DURING LATERAL FLOWS DRIVEN BY EXCESSES OR SHORTAGES OF WATER IN THE SOIL PROFILE.

De Rooij Gerrit^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Soil Physics ~ Halle (Saale) ~ Germany

Catchment-scale hydrological models make can benefit from a simple, yet physically realistic model for lateral subsurface water flows to and from surface water and drains. Ideally, the hydrological parameters should be valid directly at the aquifer scale. A theory is presented for such flows in terms of the difference between the average hydraulic head in the subsurface and the surface water level. The theory is based on analytical solutions of the linearized Boussinesq-equation. The resulting aquifer-scale flow equations are shown to be first order ordinary differential equations in which an upscaled hydraulic conductivity appears. Unlike the Darcian hydraulic conductivity, it depends on aquifer properties as well as on the forcings (recharge/extraction rate, initial and boundary conditions). Depending on the nature of recharge/extraction, the upscaled hydraulic conductivity trends to one of three asymptotic values that may be reached within a few days for realistic scenarios. Then, the aquifer-scale flow is quasi-Darcian: the flux leaving or entering the surface water is proportional to the difference between the head in the surface water and the average head in the aquifer. But a sudden change in the forcings causes deviations from the asymptotic value, and can even lead to negative and infinite upscaled hydraulic conductivities. These episodes reflect non-equilibrium conditions at the aquifer-scale, even though equilibrium at the Darcian is ensured. This is an analogy at the super-Darcian scale of the non-equilibrium that was recently simulated during Darcian-scale unsaturated flow. The causes, mechanisms and implications for this aquifer-scale non-equilibrium will be discussed.

We address primary drainage of a quasi-two-dimensional porous medium, using transparent experimental models. The entire displacement structure, as well as the amount of extracted liquid and global pressure difference over the setup, are monitored in space and time, for various imposed displacement velocities. By analyzing the geometry of the displacement structure, we obtain a scaling relation relating pressure, saturation, system size and capillary number. This scaling relation allows curves of capillary pressure versus saturation for a wide range of capillary numbers to be collapsed onto a unique master curve. The recordings of pressure and saturation are measured to be consistent with that scaling relation for all imposed flow rates. In particular, the capillary pressures's dependence on the mean displacement velocity is entirely included in the Ca-dependence of the scaling law. Consequently, this dynamic property of the measured capillary pressure results solely from the geometry of the displacement structure created by the interplay between viscous and capillary forces. This suggests that what is called dynamic effects in the literature of experimentally-measured capillary pressure curves might be explained by the combined effect of capillary pressure along the invasion front of the gaseous phase, and pressure changes caused by viscous effects, from the pore scale and up to the Darcy scale.

The Oslofjord region in SE-Norway has undergone steady glacio-isostatic uplift over the Holocene. Hence, land surface age continuously increases with elevation. A soil chronosequence on beach sand, showing progressive podzolization, is currently investigated on the western side of the Oslofjord. 31 pedons from 85 years (0.25 m a. s. l.) to 9650 years (62 m a. s. l.) are analysed. Micromorphological analysis reveals progressive accumulation of cloudy, iron-rich fine material on sand grains of the Bs horizons leading to chitonic c/f-related distribution there. In addition to podzolisation features, illuvial clay is observed below the Bs horizons. Apparently, the sand is sufficiently buffered during the first millennia of soil formation so that acidification proceeds slowly enough to allow for clay translocation prior to podzolisation. Earlier, 12 pedons in loamy marine sediments developing towards Albeluvisols were studied. Two of the oldest soils (11050 and 9000 years) exhibited initial podzolisation in their upper parts. In addition, one only 6,550 year-old soil showed beginning podzolisation. All three podzolised soils were under coniferous forest, in contrast to the other soils that were under mixed forest. The fact that another 9750 year-old soil under mixed forest was not yet podzolised, indicates that in this case the start of podzolisation primarily depends not on time but on vegetation. In conclusion, the Albeluvisol sequence includes podzolization, and the Podzol sequence shows clay illuviation preceding podzolization. These two directions of soil development are not totally exclusive in this case but may occur within the same profile to varying degree.

Understanding the mechanisms of porosity evolution during rock weathering (total porosity, connectivity, pore size) is a key issue in obtaining reliable qualitative and quantitative descriptions of weathering processes. The aim of this study was to measure the porosity development in granodiorite clasts and determine porosity and pore morphology changes with time. Samples were collected in soils of the Bishop Creek moraines, Sierra Nevada, California (Rossi et al., 2010). The soils formed a chronosequence linked to the advance and retreat of Pleistocene glaciers. The total porosity and pore morphology was measured using 14C-PMMA autoradiograph technique, including impregnation with 14C-MMA (MethylMethAcrylate), in-situ polymerization and autoradiograph (Hellmuth et al. 1993). Intensities on autoradiographs are converted into bidimensional porosity maps using 14C-PMMA calibration sources. This method allows connected porosity quantifications of the impregnated samples. Moreover, quantification of crack network changes is specifically described in terms of pore density, and pore aperture distribution (pore aperture ranging from 0.1 μ m to several mm). The results indicate that the unaltered reference sample has a total porosity of 2.61% (± 0.28 %) and a connected crack network at the grain joints. With increasing age of soil formation total porosity increases: 1.98% ± 0.57 (15.2ky), 3.96% ± 0.57 (24.3ky) 12.82% ± 1.16 (78.5ky) and 14.68% ± 2.48 (119.5ky). Apparent connectivity as well as opening of crack network increases with age in these samples. Porosity increases in a first step at inter-grain boundaries and with increasing weathering progresses within minerals due to dissolution (feldspars) or expansion (biotite). Clay minerals filling pores were also characterized to specify weathering processes.

S09.01 -3

PETROPLINTHITE FORMATION IN A QUATERNARY COMPLEX PALEOSOL ALONG NW ITALIAN COAST: FROM MICROMORPHOLOGY TO LANDSCAPE EVOLUTION

Rellini Ivano^[1], Trombino Luca^[2], Carbone Cristina^[1], Firpo Marco^[1]

^[1]University of Genova ~ Territory and Resources Study Department (Dip. Te.Ris) ~ Genova ~ Italy ^[2]University of Milano ~ Earth Sciences Department ~ Milano ~ Italy

According to the World Reference Base for Soil Classification a petroplinthic horizon is a continuous, fractured or broken layer of indurated material, cemented mainly by Fe (and in cases also Mn) and in which organic matter is either absent or present only in traces. Petroplinthic horizons are closely associated with plinthic horizons, from which they develop when exposed to repeated wetting and drying cycles. At the present time (petro)plinthite is commonly found in soils forming in subhumid tropical climates with distinct wet and dry seasons and it pertains to the material called "laterite". The aim of this work is to document the evolution of costal complex paleosol developed in NW Italy during the Quaternary, and discuss the genesis of its petroplinthic horizon, within the context of the environmental changes recorded in this sector of Mediterranean coast from the Late Pliocene to Holocene. The strong development of the paleosol sequence is mainly due to superimposed pedogenetic phases (e.g. overlapping of illuvial horizons) in an accretional landscape. In particular the petroplinthitic horizon represents the response to seasonal fluctuation of the water table, and doesn't show any genetic link with the weathered bedrock. In this light, the plinthitisation/ferruginization derived from iron enrichment and accumulation from an external upslope source, mainly by post-depositional precipitation of neo-formed iron and alumina oxyhydroxides (hisingerite), originated from the dissolution of pre-existing hematite in detrital Pliocenic lateritic soils (duricrust) fragments, which developed in higher landscape positions.

*The present study attempted to identify the origin (pedogenic, inherited, or mixed) of the calcium carbonates accumulated within mounds built by *Macrotermes falciger* (ca. 8 m in height; ca. 15 m in width), using both field and laboratory techniques. Carbonate features were investigated in a profile through the centre of a termite mound and in a cross section of an entire termite mound. Field evidence for a pedogenic origin includes the morphological type (soft powdery materials, nodules, and coatings on ped surfaces) and distribution patterns of the carbonates. Thin-section studies reveal that the carbonates occur predominantly as impregnative orthic nodules and less commonly as coatings, both clearly pedogenic; calcareous pellets are interpreted as locally reworked pedogenic carbonates. X-ray diffraction (XRD), scanning electron microscopy/energy dispersive X-ray spectrometry (SEM-EDS) and stable isotope (d13C) analyses show that all isolated carbonate features consist of high-Mg calcite (4.9-12.3 mol% MgCO₃) with d13CPDB values ranging from -13.2‰ to -11.5‰. Weddellite (CaC₂O₄ · 2H₂O) is identified in thin-section and by XRD analysis, with indications for local transformation into calcite. The stable isotope composition of carbon suggests that calcite precipitated in equilibrium with soil CO₂ generated during decomposition of soil organic matter. Locally, carbon is most likely derived from oxidation of oxalates, yielding anomalously light d13C signatures. This study proves that carbonates which accumulated in *Macrotermes* mounds are pedogenic precipitates, whose deposition is largely related to microbial decay of organic matter, subsequently redistributed to some extent by abiotic dissolution-reprecipitation and by termite activity.*

Two Chalcolithic Age burials were discovered in Southern Sardinia, Italy, within Miocene marl and Quaternary alluvial gravel deposits. The tombs included vertical access tunnels leading to funerary chambers with grave goods of the first half of the III millennium. Red staining and large patches of loose grey fibrous deposits were situated in different areas of the graves and on one skeleton. Micromorphological, organic chemical, XRD and SEM–microprobe analysis were carried out to establish whether the observed features resulted from rock/soil weathering, or from burial rituals. Investigations of the chamber vault, local weathered control materials, and within-grave samples, demonstrated that the red-stained contexts were inorganic, containing a remarkably variable quantity of iron oxides (including haematite), quartz and CaCO₃. Micromorphological analysis also showed that the fibrous grey contexts consisted of silica ‘skeletons’, where silica had replaced the original cellulose cells of monocotyledonous plant tissues, very likely from grasses that had possibly been burnt under strongly oxidising conditions (similar to what has been observed in deposits from some prehistoric and medieval sites in England). Both red-stained and grey fibrous contexts were attributed to burial rituals. Micromorphological analysis of the soil under the pelvis and head suggested that the rock and soil had been affected by burial-related decay features along a vertical, but not lateral, gradient in relation to the ground surface and burial resting plane. Micromorphology revealed in depth evaluation of materials particularly soil micromorphology yielded numerous data on processes such as formation, neoformation and transformation of minerals and microstructure in soils, pottery and construction materials. Mortars, one of the first human made materials for construction of Byzantine and the Ottoman worlds were compared in terms of micromorphology and mineralogy. The Byzantines were the first to introduce the Roman mortar/concrete, the Opus Signinum, to the eastern world as was used in prestigious buildings, where the architectural and materials production knowledge was extended to the other parts of the Ottoman world for religious complexes. Mortars of different types and compositions were widely known and used in the ancient world and the lime mortar–putty was widespread throughout the Roman and Byzantine Empires especially for earthquake resistivity. These mortars, besides being suitable for building purposes were also preferred as a water-tight layer on building mortars or to enhance the water-tight aspects of a building mortar. Adding limestone to the mix has been known to enhance the mortar strength and the formation of ettringite minerals in pores as strengtheners. The better freeze–thaw resistance of the mortars prepared with limestone and volcanic aggregates is probably due to an appropriate pore structure and sufficient mechanical strength. The processes ongoing in mortars were evaluated by soil micromorphology and archaeometry which yielded precise knowledge on the additives and new minerals formation in mortars.

LASER ABLATION(LA)-ICP-MS ON SOIL THIN SECTIONS: A POWERFUL TOOL FOR ASSESSING TRACE ELEMENT DISTRIBUTION, PEDOGENETIC PROCESSES AND SOIL POLLUTION

Scarciglia Fabio*^[1], Barca Donatella^[1]

^[1]Università della Calabria ~ Dipartimento di Scienze della Terra ~ Arcavacata di Rende (CS) ~ Italy

We recently proposed a new methodological approach for investigating trace element distribution in soils, combined with traditional micromorphological and geochemical techniques. We performed compositional spot analyses on 100µm-thick thin sections prepared from undisturbed soil samples, using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). This method was integrated with conventional observations using a polarizing optical microscope and a scanning electron microscope equipped with chemical microprobe analysis (SEM-EDS). This study, based on chemical analysis of different subportions of soil horizons (illuvial pedofeatures, pedogenic matrix and skeletal grains), permits a detailed assessment of microscale spatial variability and particle/element retention and mobility. Chemical concentrations can be measured with a high degree of accuracy and precision, reaching detection limits of 1-10 to 0.1-0.01 mg/kg, which are considerably lower than those obtained using other microanalytical techniques (EDS, WDS). We focused on behaviour of trace elements (including rare earths, heavy metals and radionuclides) in different types of silty/clay coatings and mineral or organic matrix with respect to parent rock. Main trends of increase from rock to matrix to coatings observed for many trace elements revealed a clear pedogenetic control on element fractionation, related to weathering of primary components, neogenesis of clay minerals, metal adsorption onto reactive sites of clays or organic matter, and further concentration by translocation processes of the fine fraction. In situ laser ablation techniques can be used as detailed tracers of chemical element behaviour in soils, pedogenetic/morphodynamic processes and as potential tools for assessing microsite location and mobility of soil pollutants.

Soils exhibit a structurally heterogeneous matrix across a wide range of spatial scales, whereas, processes controlling the stabilisation of soil organic matter (SOM) happen at submicron scales. Although the knowledge about the factors controlling the preservation of SOM has substantially improved, these processes are still difficult to evaluate in situ. We analysed intact soil cores from Cryosols (Typic Aquiturbel) of Northern Alaska (Barrow, USA) with nano-scaled secondary ion mass spectrometry (NanoSIMS) and VIS-NIR imaging spectroscopy. This approach enabled the combination of submicrometer-scale elemental mapping with the micrometer-scale maps of OM and mineral particle distribution. The analysis of biogeochemical soil interfaces at the submicron scale is strongly improved by the novel NanoSIMS technique. This technique allows the simultaneous analysis of up to seven ion species with high sensitivity and lateral resolution. Imaging spectroscopy is used to record the VIS-NIR reflection of a complete, undisturbed soil sample with a high spatial and spectral resolution. NanoSIMS analyses show the initial formation of aggregates and soil interfaces in the permafrost soils. A special feature are iron oxide layers in a soil core showing different amounts of sulphur indicating changing environmental conditions during their formation. Imaging spectroscopy enabled the mapping and upscaling of the micro-distribution of OM and mineral spheres to the millimetre scale. We demonstrate the great potential of a multi-scale approach for soil system research focusing on the study of soil architecture with respect to its functional properties and soil processes.

BIOGEOCHEMICAL INTERFACE DEVELOPMENT IN ARTIFICIAL SOILS

Pronk Geertje*^[1], Heister Katja^[1], Ding Guo-Chun^[2], Babin Doreen^[2], Smalla Kornelia^[2], Kögel-Knabner Ingrid^[1]

^[1]Technische Universität München ~ Lehrstuhl für Bodenkunde ~ Freising ~ Germany ^[2]Julius Kühn-Institut Bundesforschungsinstitut für Kulturpflanzen ~ Institut für Epidemiologie und Pathogendiagnostik ~ Braunschweig ~ Germany

The effect of mineral composition on the formation and properties of biogeochemical interfaces in soil was studied in a newly developed incubation experiment with so-called “artificial soils” composed of mixtures of clean and well-defined model materials. Artificial soils with 8 different compositions of illite, montmorillonite, ferrihydrite, boehmite, charcoal and quartz sand, and manure as organic matter source were inoculated with the same microbial extract obtained from an arable topsoil and incubated up to 18 months under constant temperature and water content. The formation of organo-mineral associations and microaggregates during incubation was determined by density and particle size fractionation, and the development and turnover of organic carbon and N was characterized. The CO₂ respiration was similar in all artificial soil compositions, indicating that microbial activity was limited by nutrient availability, even though the microbial communities present developed differently, depending on mineral composition and charcoal presence. Density fractionation showed that significant microaggregation and formation of organo-mineral associations took place within 3 months, and increased until the end of incubation. Solid-state ¹³C NMR spectroscopy further indicated an accumulation of proteinacious material in the fine fractions of the artificial soils. Overall, the artificial soils developed quickly into aggregated systems with established microbial communities of soil-like complexity, that contained different habitats for microorganisms depending on composition. The artificial soils therefore provided a useful and well-defined model system in which the formation and maturation of biogeochemical interfaces in soil could be studied.

*The plant litter-soil interface is characterised by a constant turnover of plant material and the concomitant release of alkanes (as major constituents of the waxy plant tissue) to soil microbes. Here, we describe community changes of alkane-degrading bacteria harbouring and expressing the alkane monooxygenase gene *alkB* in response to either maize or pea litter at different soil microsites neighbouring the plant material (litter layer; soil-litter interface; soil layer 1-1.5 cm below interface). In microcosm experiments spatio-temporal changes of released alkanes were analysed over a period of 30 weeks and related to bacterial community changes in a cambisol and a luvisol, respectively. Bacterial communities were analysed by cell enumeration and a T-RFLP method targeting *alkB* genes. Both the number and community composition of alkane-degrading bacteria varied significantly in litter-amended soils: Alkane availability and the microsite relative to the plant litter source correlated with the spatio-temporal community changes on the DNA-level. By contrast, poor impact of soil type was observed. The expression of *alkB* genes (RNA-level) however significantly depended on the soil type which considerably influenced the alkane quality. Furthermore, the community profiles on the RNA-level were remarkably similar in litter and soil layers indicating common active degraders at the different microsites. We consequently hypothesise that the soil-litter interface is a hotspot for microbial alkane-degradation which also shapes the natural alkane-degradation rates and potential in the soil zones underneath. Moreover, litter-addition to contaminated soils would actively create soil-litter interfaces thus enhancing the intrinsic alkane-degradation capacity in terms of a biotechnological approach.*

Soil particle wetting properties play an important role for the development and the functioning of biogeochemical interfaces as they control the spatial distribution and continuity of the fluid phases in the soil matrix. In turn, the wetting properties can be modified during soil development by sorption of organic substances. To investigate the role of wetting properties and their alteration during initial soil formation processes we perform percolation experiments with columns composed of an organic top-layer as a source for dissolved organic matter and a downstream reception layer consisting of pure mineral particles. Before and after percolation with a CaCl₂ solution for several weeks, the entire column was investigated by X-ray μ CT at a resolution of 0.1 mm for pore structural changes and formation of flow paths. Then the mineral part of the column was sliced in 1 cm thick layers and air-dried. The wetting properties of the exposed surfaces were evaluated by contact angle measurements at a high spatial resolution with the sessile drop method. Experiments with O horizon material as source layer and a quartz/illite mixture as mineral receptor layer showed that leaching results in spatially heterogeneous sorption of organic substances on mineral particles, optically visible as dark spots. These locations are characterized by a distinctly decreased wettability with contact angles up to 80° while the surrounding material has not been altered in its wetting properties. The experimental procedure allows us to allocate soil interfacial properties with respect to their location within the three-dimensional structure of the pore space.

Soil structure is a significant resulting characteristic of soil bio-functioning. Thus, imaging structure, by describing the spatial organization of pores and aggregates, can help to understand the evolution of soils submitted to different impacts, especially as these investigations are realized at different scales. In this way, we combined morphological and analytical characterization of organo-mineral structures at two different scales (1) of soil thin sections by using light microscopy and SEM/EDX and (2) of 0-50 μ m soil fractions by using TEM/EDX. By this approach, we highlighted the role of biological activity on soil structure in agrosystems or more anthropised soils, such as: -

the root impact on the genesis of stable aggregates in a silty soil under maize underlining the part of the nature and the humification state of the root organic matter - the impact of rhizospheric activity (root, earthworm and bacteria) on the structure of a constructed Technosol resulting from the combination of paper-mill sludge, thermally treated soil material and green waste compost - the contribution of the mesofauna activity, e.g. Oribatid mites, through their faecal pellets to the re-distribution of pollutants (Pb, Zn, Mn) in the humus layer of a Technosol developed on a settling pond used in steel industry for blast furnace sludge forage. Such results gave relevant in situ information on the state and availability of the organic matter and associated elements involved in aggregates.

**ORGANO-MINERAL ASSOCIATIONS IN AN ANDISOL DEVELOPED FROM VOLCANIC ASHES
(PART 1): DOES PARTICLE SIZE MATTER?**

Asano Maki^{*[1]}, Wagai Rota^[1]

^[1]National Institute for Agro-Environmental Sciences ~ Carbon & Nutrient Cycling Division ~ Tsukuba ~ Japan

Volcanic-ash soils are characterized by a high content of soil organic matter (SOM) and consist mainly of short-range-order minerals such as allophane, imogolite and ferrihydrite. Allophane/imogolite are unique nanoclays of hollow spherule/tube structures with the diameter of <5 nm and have high AEC and CEC as well as extensive, variable-charge surfaces. Due to the dominance of these nanoclays, SOM stabilization process in volcanic soils may differ from that in non-volcanic soils consisting of well-crystalline minerals. Particle-size fractionation is an effective approach to distinguish different types of organo-mineral aggregates and to elucidate SOM stabilization processes. However, because these nanoclays form sonication-resistant aggregates, the effectiveness of this approach on volcanic-ash soils remain obscure in the literature. Here we hypothesized that, with an appropriate dispersion technique, major portions of SOM is stabilized in finer size fractions (<2 μm) as sub-micron aggregates of short-range-order minerals with microbially-processed organic matter in volcanic-ash soils. To test this, we chose a surface (Ap) horizon of typical allophanic Andisol in Japan. We compared dispersion techniques (sonication at several levels and chemical treatments), analyzed each particle-size fraction by selective-dissolution, isotopic (N-15, C-13, C-14), and spectroscopic techniques, and found strong particle-size control on the physicochemical nature of organo-mineral aggregates. Together with the results from a companion study (Wagai et al., in the same session) which used sequential density fractionation approach, we speculate on the progression in organo-mineral associations from fresh plant detritus to the organo-mineral aggregates of varying stability for the volcanic-ash soil studied.

Nitrification process, being involved in plant N nutrition and N losses through leaching and denitrification of nitrate, plays a key-role in ecosystem functioning and particularly in N-limited ones like wet tropical savannas. Regulating nitrification is thus central to any strategy for improving NUE. Biological Nitrification Inhibition is an active plant-mediated natural function, where nitrification inhibitors released from roots suppress soil-nitrifying activity, thereby forcing N into other pathways. 20-years studies in Lamto savannas (Ivory Coast) showed that they exhibit two different types of N cycle, with high- and low-nitrification sites. The dominant perennial grass, Hyparrhenia diplandra, is mainly responsible for this duality at subpopulation level, with one widespread ecotype being able to inhibit nitrification causing the general low nitrification status of savannas. The other is less common, unable to reduce nitrification and leads to the existence of nitrifying zones. At rhizosphere scale, we demonstrated high sensitivity negative or positive relationships depending on ecotypes between root densities and nitrification. At plant scale, the different nitrification rates led to huge differences in NUE that can explain differences in primary production that is 2-times higher for nitrification inhibiting subpopulation. These differences are at least partly explained by different plant intrinsic growth characteristics. Finally, at landscape scale, all grass species mainly expressed an inhibiting effect but inversely, all tree species expressed a very high stimulation impact, with nitrification up to 377-fold greater near trees. All these inhibition/stimulation effects of biotic landscape elements seem site-dependant, linked to the overall baseline nitrification level of the two systems.

IS ORGANIC NITROGEN UPTAKE A RELEVANT N SOURCE FOR PLANTS?

Moran-Zuloaga Daniel*^[1], Dippold Michaela^[1], Kuzyakov Yakov^[2]

^[1]University of Bayreuth, Germany ~ Department of Agroecosystem Research, BAYCEER ~ Bayreuth ~ Germany

^[2]Georg-August-University of Göttingen ~ Soil Science of Temperate Ecosystems ~ Göttingen ~ Germany

Some recent studies suggested that in beside to inorganic nitrogen plants can also take up organic N, but ecological relevance or this N source is not yet clarified. The aim of this study is to understand the significance of organic N uptake by three agricultural species: maize (Zea mays), chicory (Cichorium intybus) and white lupine (Lupinus albus). To understand the fate of Low Molecular Weight Organic Substances (LMWOS) ¹⁵N and ¹⁴C labeled alanine (uniformly and position-specifically labeled) were injected into the rhizosphere. N free LMWOS (acetic acid) and inorganic ¹⁵N were used as control. The significance of organic N uptake and the fate of LMWOS were evaluated based on ¹⁴C and ¹⁵N content in soil, shoot and root biomass as well as in respired CO₂. For the N free LMWOS (acetic acid) the uptake was higher for C1 group than for C2. This is a result of fast decarboxylation and release of HCO₃⁻ which was taken up passively. For amino acids the uptake percentage ranged from 0.01-0.05% of the added alanine with C3>C2>C1, i.e. no preference for the carboxylic group was observed. Position-specific differences were obtained only in maize and lupine, which might indicate a specific and fast uptake of alanine by chicory. In summary, these results showed that there are position-specific differences in LMWOS utilization of maize, chicory and lupine. This reveals that N nutrition by LMWOS is a complex process and mechanisms as well as influencing factors have to be investigated to assess its relevance in field.

FORAGING IN NUTRIENT PATCHES: ARBUSCULAR MYCORRHIZAL FUNGI, THE PLANT'S EXTENDED ROOT SYSTEM.

Hammer Edith*^[1], Wallander Håkan^[1], Nasr Hafedh^[2]

^[1]Lund University ~ Microbial Ecology ~ Lund ~ Sweden ^[2]National Research Institute for Rural Engineering, Water and Forest ~ INGREF ~ Tunis ~ Tunisia

Soil is a very heterogeneous substrate, and especially its organic matter fraction can be very unequally distributed. We examined the influence of different organic matter- and nutrient patches on the extended parts of plant's root systems: arbuscular mycorrhizal fungi (AMF). Experiments were conducted in field in semi-desert soils in Tunisia and under controlled sterile laboratory conditions. Organic matter patches, inaccessible to the host plant roots, stimulated AMF more strongly than mineral nutrient patches, even though they - as obligate biotrophs – are not dependent on organic matter as an energy source. Also the plant's investment in form of carbon flow to the rhizosphere (to AMF, rhizobia and other soil bacteria, measured by ¹³C pulse labelling) was strongly enhanced by organic matter patches. Under sterile conditions, mineral nutrient patches as P and K attracted and amplified AMF growth, while patches of high salinity, inhibited AMF. Even sterile soil and charcoal promoted AMF growth. Nutrient uptake and storage was investigated with proton induced x-ray emission (PIXE) analysis, allowing to map the elemental composition of the tissue.

S10.01a -4

SOIL ARCHITECTURE CONTROLS THE PLANT AVAILABILITY OF P IN FOREST SOILS

Voß Ivo^{*[1]}, Lang Friederike^[1]

^[1]Tu Berlin ~ Institute of Ecology/Department of Soil Science ~ Berlin ~ Germany

The structure of soils is partly regulated by plant roots and their exudates. There is also evidence that the availability of Phosphorus (P), being a strongly sorbed and immobile nutrient depends on soil structure. We hypothesized that (i) the diffusion of P out of small aggregates limits its mobilization and (ii) that the effect of this structure-limited P mobilization increases with increasing aggregate stability. We analyzed two sandy topsoil samples and two loamy topsoil and subsoil samples in an end-over-shaking batch experiment. We determined P desorption kinetics by anion exchange resin of aggregated soil samples and of soil samples dispersed by ultrasonic treatment. After different times of extraction we determined aggregate size distribution and amount of mobilized P. When compared to standard chemical dispersion, ultrasonic breakup of aggregates resulted in similar grain size distribution, indicating complete dispersion of aggregates. There was no difference in P mobilization between the dispersed and non-dispersed sandy topsoils whereas we observed a significantly slower P mobilization in the aggregated loamy soils. Other than expected the difference in P mobilization was smaller in the topsoil which shows more stable aggregates than the subsoil. We explain this effect with a possibly higher porosity of aggregates in the topsoil resulting in a smaller diffusion resistance or/and P accumulation on aggregate surfaces in these samples. Our results emphasize the relevance of soil aggregation for P availability. Thus further research should consider the ability of plants to control nutrient availability via the pathway of influencing soil architecture.

S10.01a -5

MODELING MINERAL NUTRIENT UPTAKE OF SPRUCE TREE ROOTS AS AFFECTED BY THE ION CONCENTRATION CHANGES IN THE RHIZOSPHERE: UPSCALING OF MODEL RESULTS TO FIELD PLOT SCALE

Nietfeld Heino^{*[1]}

^[1]Georg August University ~ Soil Science of Temperate and Boreal Ecosystems ~ Göttingen ~ Germany

A multi-ion rhizosphere model has been developed which describes the reactive transport of all major ions in the rhizosphere. The model is used in a Monte Carlo upscaling approach to calculate the heterogeneity of the actual nutrient uptake rates (U), the H/OH root excretion rates and the ion concentrations in the inner rhizosphere (Rh ; 2.0 mm soil volume around the root). The variability of the model parameter values has been derived from measurements conducted on the F1 spruce-plot in Solling, Germany. Rh -to-Bulk ratios (Rh -enrichment factors) of modeled and measured Rh -concentrations (F1-plot) are determined. The Rh -enrichment factors around non-mycorrhizal long roots cover a range between 0.5 and over 3.0 (Nietfeld et al., 2011a; Nietfeld et al., 2011b; submitted) depending on the ion considered and are characterized by a high short-term dynamics. Around mycorrhizal roots mostly ion depletions in Rh have been modelled (Nietfeld et al., in prep.) which are due to the uptake activity of the emanating hyphae. Modeled enrichment factors agree with enrichment factors determined by measured Rh -concentrations. Around long roots mostly OH -root excretions have been calculated which cause depletions of exchangeable protons or exchangeable aluminum ions; the latter one is determined by the formation of $Al(OH)_3$ (gibbsite). At OH root excretions the U -rates of Mb cations (Ca , Mg , K) are considerably smaller than the Mb root uptake capacities. This is caused by small desorption rates of exchangeable Mb cations which is due to depletions of exchangeable H or Al ions.

DATA GATHERING FOR MODELING THE NUTRIENT ACQUISITION FROM THE SUBSOIL: CARBON AND NITROGEN CONTENTS OF THE DRILOSPHERE

Kautz Timo^{*[1]}, Athmann Miriam^[1], Perkons Ute^[1], Köpke Ulrich^[1]

^[1]University of Bonn ~ Institute of Organic Agriculture ~ Bonn ~ Germany

Biopores are considered to play a major role for the nutrient acquisition from the subsoil. Within the DFG research unit 1320 'Crop sequence and the nutrient acquisition from the subsoil', data are collected for modeling nutrient mobilization, uptake and turnover in the subsoil. To characterize the drilosphere with respect to C and N contents, individual biopore coatings and loose soil material inside the pore volume (biopore fillings) were sampled in 45-55cm, 55-65cm, 65-75cm soil depth by taking soil monoliths of 2500 cm³ volume each and three repetitions per depth. Total C and N contents of the individual samples (elementary analysis, Euro EA 3000, HEKAtech, Germany) were related to C and N contents of bulk soil samples of the same soil volume. In all biopore coatings and fillings analyzed, C and N contents were higher than in the bulk soil. Nevertheless, the individual values fluctuated in a big range (compared to bulk soil samples: factor 1.02-3.03 for C and factor 1.02-2.69 for N). A significant correlation between C and N contents of coatings and of fillings collected within the same biopore was determined. The results show that a detailed consideration of nutrient contents in biopore coatings and fillings is necessary for precisely quantifying the contribution of the drilosphere to the nutrient acquisition from the subsoil. More research is needed to relate genesis and further usage of the individual biopores by plant roots and earthworms to nutrient contents.

*The parallel understanding of dissolved organic matters (DOM) impact on trace metal speciation in soil and root ability to change DOM concentration and composition in the rhizosphere strongly suggests a substantial alteration of metal binding capacity of DOM in the rhizosphere, with consequent impacts on metal phytoavailability. This hypothesis is investigated in the present communication on the basis of two independent set of experiments. Both experiments used the RHIZOtest experimental set-up, which enables an easy and fast recovery of both plants (i.e. shoots and roots) and rhizosphere, to grown either lettuce (*Lactuca sativa*) or durum wheat (*Triticum turgidum durum*) on two different soil samples notably varying in pH, organic matter content and geographical origin (tropical vs. temperate area). Usual chemical properties (i.e. pH, concentration of DOM, major cations/anions and metals) and free copper activity were measured in the rhizosphere solution. Copper speciation was then modelled in the rhizosphere solution with the humic ion-binding model VI (Model VI) by adjusting the metal binding capacity of DOM to fit experimental data. Compared with bulk soil measurements, a large increase in both pH and DOM concentration was observed in durum wheat rhizosphere while these two parameters did not change significantly in lettuce rhizosphere. Alternatively, the fraction of DOM involved in copper binding decreased similarly by 40 % in both durum wheat and lettuce rhizosphere. These very convergent pictures of a decrease in metal binding capacity of DOM in both experiments lead to discuss the hypothetical governing mechanisms and the genericity of this finding.*

LMW organic compounds (e.g. organic acids, amino acids, etc.) released by living plant roots are known to significantly contribute to the development of chemical, physical as well as microbial rhizosphere gradients. Suitable and accurate sampling procedures are therefore crucial in order to better understand root exudate driven dynamics of rhizosphere processes. The aim of this study was to compare commonly used sampling techniques including a novel exudate collecting tool that allows non-destructive and repetitive collection of unaltered root exudates from a root mat developed in rhizoboxes. Root exudates from Zea mays were collected using the following experimental designs: (i) hydroponic growth & sampling, (ii) soil growth & hydroponic sampling (iii) micro-suction cups in a high spatial resolution and (iv) rhizoboxes combined with the novel in-situ root exudate collecting tool. The effect of different sampling solutions (deionised H₂O & 0.5 mM CaCl₂) on the exudation patterns of organic and amino acids was also compared. Results showed that exudation rates differed qualitatively and quantitatively between soil-grown and nutrient-solution-grown plants with higher exudation rates being observed from soil grown plants and a better exudate compound recovery in H₂O. Soil solution concentrations obtained from micro-suction-cup sampling in defined distance to the root surface showed a decrease in exudate concentration towards the root surface probably due to higher microbial activity in the rhizosphere compared to the bulk soil. Rhizoboxes combined with an exudate collecting tool show great potential to further elucidate the complex root exudation dynamics of soil grown plants.

THE ROLE OF ROOT EXUDATES IN CHANGING SOIL MINERALOGY AND MOBILIZING TRACE ELEMENTS

Terzano Roberto^[1], Medici Luca^[2], Lettino Antonio^[2], Fiore Saverio^[2], Mimmo Tanja^[3], Tomasi Nicola^[4], Pinton Roberto^[4], Cesco Stefano^[3]

^[1]University of Bari ~ Department of Agroforestry and Environmental Biology and Chemistry ~ Bari ~ Italy ^[2]I.M.A.A.-C.N.R. ~ Institute of Methodologies for Environmental Analyses ~ Tito Scalco (PZ) ~ Italy ^[3]Free University of Bozen ~ Faculty of Science and Technology ~ Bozen ~ Italy ^[4]University of Udine ~ Department of Agricultural and Environmental Sciences ~ Udine ~ Italy

Root exudates such as low molecular weight organic acids (e.g. citric acid, malic acid, oxalic acid), phenolic compounds (e.g., flavonoids), and siderophores of microbial or plant origin can alter soil mineralogy in the rhizosphere thereby releasing trace elements in solution, which can act as essential micronutrients or dangerous pollutants for plants. This research assesses the effect of various root exudates (citric acid, malic acid, oxalic acid, genistein, quercetin and siderophores) on the mineralogy of two different soils (an agricultural calcareous soil and an acidic polluted soil) and evaluates possible synergic or competitive behaviors. X-ray diffraction (XRD) coupled with Electron Probe Micro Analysis (EPMA) was used to identify the crystalline and amorphous phases which were subjected to mineral alteration when exposed to the action of root exudates. Solubilization of trace metals such as Cu, Zn, Ni, Cr, Pb, Cd as well as of major elements such as Si, Al, Fe and Mn was assessed by means of Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES). It was also found that soil microorganisms attenuated mineral weathering by reducing the concentration of active root exudates in solution. This information is an important cornerstone to better understand the biogeochemical processes acting in the rhizosphere which can play an important role in the availability of trace elements (either nutrient or toxic) for plant acquisition. Research supported by MIUR – FIRB “Futuro in ricerca” (RBFR08L2ZT), internal grant of Unibz (TN5031) and Provincia BZ Rhizotyr TN5218.

*Soil structure is an important factor for soil quality and productivity by providing “healthy” interactions between physical functions and soil biota. One of the main aspects in soil structure is soil aeration, as it influences microbiological activity and root respiration. In this work we analyzed the ability of three root systems for generating macropores thus improving soil aeration: shallow roots (*Festuca arundinacea*), taproot-herringbone (*Cichorium intybus*) and taproot-multibranch (*Medicago sativa*). Soil aeration was determined by gas diffusion, air permeability and air capacity measurements on undisturbed soil cores at different matric potentials and depths. Microdiffusivities in the meso-micropores were measured with Clark-type microelectrodes. By means of computer tomography, connectivity and tortuosity of pores could be determined in vertical and horizontal directions. A field monitoring system allowed determining water saturation in soil which combined with laboratory measurements was used to derive in situ critical aeration conditions. Results show a better aeration of the topsoil with the shallowroot crop and in the subsoil with the taproot crops. *Medicago sativa* had a significant influence on the aeration below 60cm depth as it creates deeper and more continuous macropores than the other two species.*

DROUGHT AND WATER STRESS OF CROPS: A LOOK AT THE SOIL-ROOT SYSTEM INTERPLAY

Doussan Claude*^[1], Iyad Srayeddin^[2]

^[1]INRA ~ UMR EMMAH - INRA/UAPV ~ Avignon ~ France ^[2]Damascus University ~ Soil Science ~ Damascus ~ Syrian Arab Republic

Climate change may induce in parts of the world a decrease of rainfall. Such a change is already at work in the Mediterranean region where a decrease in rainfall rate seems to have started 40 years ago. Likewise, drought and particularly extreme drought could increase in a near future, like the 2003 heat and drought wave over Europe. As a consequence, rainfed crops or natural ecosystems will be more often drought stressed but, also, irrigated crops because of the increasing pressure over renewable water resource. There is always a need to increase the efficiency of water uptake by plant. In the different component of water efficiency of plant or crop, the soil-root system is less known and lots remain to be gain in the efficiency of water use by a better knowledge of the soil-root system interplay. With experimental data of two crops, Maize and Sorghum which exhibit different susceptibility to drought stress, we will show the difference in development of root systems of the two crops in conjunction with water use for variable water stress levels. Some emphasis will be given to the spatial variability of uptake, with the use of new imaging techniques like Electrical Resistivity Tomography. We will conclude by a look on new experimental or modelling avenues that could be helpful in improving our knowledge and optimisation of crops (and soil) in facing drought stress.

IMPACTS OF ROOT SPATIAL DISTRIBUTION ON PHYSICAL & HYDRAULIC PROPERTIES IN PEAT GROWING MEDIA USED IN HORTICULTURE

Cannavo Patrice*^[1], Michel Jean-Charles^[1]

^[1]Agrocampus Ouest, Centre d'Angers ~ UR EPHor ~ Angers ~ France

Plants growing in pots are generally limited by the volume of substrate in which water and gas availability can fluctuate over a short period of time. The hydraulic properties of growing media generally provide precise information about their ability to guarantee good growth conditions. However, the root development and the heterogeneity of their distribution raise the question of the evolution and heterogeneity of hydraulic properties inside the pot. We monitored a 110-day experiment in a greenhouse, by using two peat growing media -mainly used in the world- with 2 particle sizes (0-10 mm and 20-40mm) and rose "knock out" growing in 1.1L cylindrical pots. Three layers (H1 0-3cm, H2 3-6cm, H3 6-10cm) were defined and each one was divided into 2 parts, the internal zone (3cm radius), and the external zone (rest of the layer). In each of the 6 zones, the volumetric root content, the water retention and hydraulic conductivity curves, tortuosity and the relative gas diffusivity were analysed. Peat particle size did not affect the root volume (6% at day 110). A low air-filled porosity (<0.1 v/v) in all zones of the fine peat was observed at the end of the experiment, whereas only H3 layer was affected in the coarse peat. Tortuosity was the highest in the coarse peat, with high variations depending on the zone. Roots tended to decrease tortuosity favouring a better water conductivity, but also decreased the relative gas diffusivity, especially at the base and the border of the pot.

*Recently, the application of X-ray microCT for rhizosphere research has gained considerable attention due to the ability to visualise in situ root-soil interactions without disturbance. The aim of this research was to quantify the spatio-temporal effect of compaction and drought on root growth. Using tomato (*Solanum lycopersicum*) as a model plant we used X-ray CT at 10µm with daily scanning for several weeks to measure the effect of soil compaction and drying conditions on root elongation and other root traits. The treatments included soil type, bulk density and the effects of layering (total number of scans was c. 500). A new in-house root tracking algorithm, Roottrak, was used for image segmentation overcoming previous limitations associated with the overlap in attenuation values with roots and water filled pores. Soil compaction significantly affected root volume ($P<0.001$) over time. Plants in compacted soil had reduced volume and length ($P<0.01$), but a greater root diameter ($P<0.05$). Visualising the rhizosphere soil under drying conditions illustrates the variability in root-soil contact across short time scales. CT in combination with root phenotyping approaches supports enhanced understanding of the influence of abiotic stresses on root growth which will feed through to improvements in plant breeding programmes.*

Drip irrigation is used in 'Conference' pear tree in Belgium and the Netherlands to maximize fruit size in dry years. Besides regulated deficit irrigation, partial root zone irrigation (PRI) is an irrigation strategy used for increasing the water use efficiency. Trees under PRI take up more water in the irrigated part compared to the non irrigated part. However the importance of this "compensation effect" and the magnitude of this effect on tree transpiration on an irrigated tree in a temperate climate is unknown. To evaluate the impact of compensation in the pear tree root system, the root water uptake pattern was obtained in HYDRUS 2D using the dimensionless water stress index ψ_c (Jarvis 1989), recently implemented in HYDRUS. For the simulation detailed observations of soil hydraulic properties and root distribution were carried out. Simulation results were compared to measurements of soil hydraulic head and soil water content as well as sap flow rate in the trunk. Evolution of soil hydraulic head was successfully simulated for a non irrigated and partially irrigated tree for a period of 87 days. During this period, soil hydraulic head did not drop below 450 cm while it decreased to -800 cm for the non irrigated treatment. Water stress was observed in the non irrigated treatment but not in the partial irrigated treatment. Simulations with HYDRUS indicate that compensation did not interfere with the course of sap flow nor with the soil moisture content evolution.

ROOT WATER UPTAKE IN HETEROGENEOUS MEDIA

Kuhlmann Anna*^[1], Neuweiler Insa^[1], Van Der Zee Sjoerd^[2]

^[1]University of Hannover ~ Institute of Fluid Mechanics and Environmental Physics in Civil Engineering ~ Hannover ~ Germany ^[2]Wageningen University ~ Soil Physics, Ecohydrology and Groundwater Management, Environmental Sciences Group ~ Wageningen ~ Netherlands

To predict flow in the unsaturated zone with respect to environmental problems, models are needed which are preferably simple but account for important factors such as heterogeneity of the soil and water uptake by plant roots (RWU). The presentation compares different approaches for RWU in heterogeneous media to discuss how complex RWU models on large scales need to be. Flow in the unsaturated zone is modeled with the Richards equation. The variability of the soil parameters is modeled by a stochastic approach, where the soil parameters, such as saturated hydraulic conductivity, are described as correlated random fields. If the RWU rate is modeled according to a standard macroscopic approach as sink term in the Richards equation determined by atmospheric demand, root density and stress-reduction factor (according to the Feddes-function), extremely dry regions occur in fields with large lenses of coarse material. These spots lead to large variances of the pressure head and reduce the global uptake of roots. This rather doubtful result rises the question if such a strongly simplified concept for RWU is applicable to heterogeneous media or if small scale processes such as soil physical and plant physiological mechanisms have to be taken into account. Therefore, simulation results obtained with the standard macro-model for RWU are compared to simulations where the wilting point depends on the soil properties, and to simulations with a micro-model where root architecture and growth mechanisms are included.

Soil hydraulic properties are subject to several environmental and management influences. Therefore they generally show high spatial and temporal variability, particularly in the range of structural porosity. Plant roots have been described as driving forces for the formation of soil structure and porosity at different scales. A major difficulty in quantifying root-soil interactions in the structural range however is their high spatial variability. A better quantitative understanding of root effects on soil hydraulic properties could allow a more targeted use of plants for soil protection and improvement of soil structure. The objective of this study is to provide quantitative evidence for the role of roots for structural porosity and to analyze the plant impact compared to other environmental driving forces of soil structure. We measured soil hydraulic properties in the near saturated and structural range under plants with different root systems using a tension infiltrometer and a capillarimeter in a spatial measurement design. Plant roots were quantified using image analysis. Data will be compared to measurements of temporal hydraulic property dynamics to analyze the magnitude of root effects in relation to other environmental impacts on structural porosity. Finally a model will be presented that allows studying hypothesis on root effects on the soil pore system and their consequences for water flow in the soil.

A better understanding of root-soil interactions and associated processes is essential to achieve progress in crop breeding and management. To date it is still difficult to analyze root growth and function in the field because of a lack of satisfactory non-destructive monitoring methods. A promising technique in this respect is electrical impedance tomography (EIT), which utilizes electrical conduction and polarization properties – here of the root-soil system – in an imaging framework. We investigate the capability of laboratory-scale EIT to image crop root growth in rhizotrons by comparing the electrical imaging results with those obtained from established optical methods. A series of experiments were done in soil-filled containers of 80 × 30 × 2 cm³ size using wheat and oilseed rape as model plants. In each experiment root growth was monitored daily over several weeks using EIT and the custom-made image analysis system GROWSCREEN-Root. EIT data were collected with the acquisition system Medusa-II and EIT images were computed with the complex resistivity inversion code CRTomo. Root growth parameters were additionally validated using the software WinRHIZO. Correlations between EIT imaging data, optical readings and root growth parameters were analyzed. The results demonstrate the capability of EIT to image root growth at rhizotron scale and suggest that EIT can be developed into a non-invasive tool for imaging and monitoring of crop roots at the field scale. The presented work is part of the subproject ImpTom, funded by DFG within the research Unit FOR 1320 “Crop Sequence and Nutrient Acquisition from the Subsoil”.

Water uptake of plant roots is monitored using non-invasive imaging by Nuclear Magnetic Resonance Imaging (MRI). The evaluation of observed patterns and conclusions on the underlying mechanisms require further comparison with numerical simulation using basic physical principles on water fluxes in soils. This also requires an unambiguous reconstruction of the entire root system from the partly noisy and discontinuous 3D information. In this paper we compare two methods for doing this: a manual method using 3D virtual reality system with manual tracking of root strands and an automated image processing method. The procedures are elucidated on the basis of 3D MRI images of maize and lupin root systems in sand and loamy sand soils with a resolution of 0.39 mm combined with images of water content changes over a period of 2 weeks during increasing drought stress. Both reconstruction methods yield similar root architectures which are validated with standard parameters like root length density determination. The simulated water uptake patterns show first that the reconstructed root systems can be used as input and second that calculated and experimentally observed water content changes agree. The desiccation patterns are rather uniform during the initial stages of transpiration, only near the end stronger depletion in the rooting zone is observed. Reason is the always sufficiently high hydraulic conductivity of the soil, and one may conclude that the bottleneck for root water uptake is the transfer bulk soil to roots.

The influence of the soil on vine behaviour and wine quality is complex, because the soil properties affect vine mineral nutrition and water uptake conditions, but also rooting depth and temperature in the root zone. The aim of this study was to analyze the quality of the must in different soil groups determined by the winery. The study was carried out in 2009 and 2010 on the vineyards of the winery Bodegas y Viñedos Labastida which covers an area of 525 ha. Prior to this study the winery had classified soils in four groups (based on a soil map of the zone) depending on their yield and quality behaviour of the vineyard over time, which differs mainly in the soil's water holding capacity. In the years 2009 and 2010 at 300 and 270 grape samples respectively the following quality parameters were measured: weight of 100 berries, malic acid, tartaric acid, pH, K, anthocyanins and colour intensity. Statistical analysis was performed using a HJ-Biplot. Different types of soil did not show the same qualitative behaviour of the must. Furthermore, it can be differentiated soils with lower water holding capacities since they presented musts with higher alcohol and tonality and higher anthocyanin content, from soils with higher water holding capacities which presented musts with higher levels of malic acid.

The work presented here is the result of a research project aimed to define a geochemical marker suitable to associate the wine to its grape terroir. We determined Sr isotope ratios in a number of microvinifications on single grapevines belonging to the “Azienda Barone Ricasoli” at Brolio, during the 2008 and 2009 grape harvest, together with the soil portion underneath each single grapevine. Our results demonstrate an excellent reproducibility of the $^{87}\text{Sr}/^{86}\text{Sr}$ values of each sampling point in the two harvesting years suggesting that the Sr uptake process from the grapevine roots to the wine is time independent. Furthermore, we find a small-scale, albeit detectable, variability of $^{87}\text{Sr}/^{86}\text{Sr}$ values among the different sampling points. This variability is due to both the heterogeneity of the geological substratum of the vineyard, and the isotopic change of the leachable Sr fraction from the soil. $^{87}\text{Sr}/^{86}\text{Sr}$ values on soils are similar to the corresponding wine despite some scattering. They show a consistent trend with the Sr-isotope ratios characterizing each wine on each sampling point, corroborating that wines inherit their inorganic elements from the soil parent material on which each vineyard is embedded. The $^{87}\text{Sr}/^{86}\text{Sr}$ value can safely represent a meaningful parameter and an extremely promising isotope-geochemical tracer in the analysis procedure to guarantee the geographic origin and the production terroir of wines. To corroborate our results, we also consider other high-quality wines of the Italian territory, such as Chianti Classico, Cesanese, Aglianico del Sannio and Aglianico del Vulture for comparison.

Water nutrition is crucial for wine grape performance. Thus soil investigation aims at characterizing spatial and temporal variability of available water. A possible strategy is to integrate monitoring and proxies of water availability. The carbon isotope ratio DC13, measured in the alcohol of wine, is a promising tool to determine water stress during the vine growing season and vine performance. A research study was set up to evaluate the relationships between DC13, soil water deficit, and wine grape viticultural and oenological performance. The trial was carried out for three years in the Chianti Classico wine production district (Central Italy), on not irrigated vineyards of a premium farm. The reference variety was Sangiovese. 11 sites were chosen for vine monitoring and grape sampling. The performance parameters were sugar content, sugar accumulation rate, mean berry weight, and extractable polyphenols. DC13, stem water potential, and soil water deficit, as difference between soil water content, monitored during the veraison-yield, and the standard wilting point, were measured. DC13 resulted directly related to stem water potential and soil water deficit, and showed absence to only moderate water stress. However, the relationship with viticultural and oenological results was contrary to the expectation, that is, the performance increased when the water stress decreased. The explanation was that the viticultural husbandry was so competing for the plants (high plant density, high pruning, weak rootstock, grass cover) that the effects of water stress on grape quality were magnified. In conclusion, DC13 cannot be directly used to estimate vine performance.

S10.02 -4

REALISATION OF TERRONS IN THE LOWER HUNTER VALLEY, AUSTRALIA

Hughes Philip^[1], Mcbratney Alex^{*[1]}, Malone Brendan^[1], Minasny Budiman^[1]

^[1]The University of Sydney ~ Faculty of Agriculture, Food & Natural Resources ~ Sydney ~ Australia

The recent globalisation of the wine industry has seen the expansion of New World wines on the international market. In order to improve the profitability of the Hunter Valley, Australia as a wine growing region and tourist destination, recognition and marketing of viticulture terroirs is a worthwhile endeavour. This study sought to define terrons with the view to delineating terroirs in the Hunter Valley. A terron is a relatively new soil mapping concept that combines soil and landscape data to create continuous soil classes, which are ascribed memberships to groups based to the relative strength of their attributes. Soil-landscape attributes of important to wine-growing were derived using digital soil mapping technologies from the field observations combined with the environmental covariates. One of the most important attributes measured was marl, a lime bearing rock which is a constituent of good wine making soils. The remaining data included land class, subsoil pH, readily available water and drainage. Based on these landscape attributes, the area was grouped into classes that have similar properties using fuzzy k means algorithm. These classes were interpreted as a terron map of the Hunter Valley winemaking region. This terron map was shown to local vigneron who were asked to assess the terron map for accuracy. From this it was determined that not only had the terron map accurately predicted identifiable attributes, such as the presence of marl, but it had also correctly depicted the characteristic of individual soil taxa described in the terron model.

The ZOViSA Project (Viticultural zoning at farm scale) tests a new methodology for the viticultural zoning at farm scale integrating the classical pedological approach, the study of soil hydrological processes and the use of physically based agro-hydrological model. The project is conducted in two farms of southern Italy (Del Monte–Ponte(BN) and Quintodecimo–Mirabella Eclano (AV)) located in the Campania region and devoted to quality wines production (Aglianico and Falanghina DOC). One task of the project is to study the effects of soil-plant water status (e.g. soil water stress) on wine quality, through the use of simulation model SWAP. This latter allows estimating soil-plant water status in different crop phenological stages. Moreover, its use is fundamental to extend the approach from stand scale to farm scale, becoming also an important forecasting tool to support the farmer decision. In one site (Quintodecimo farm) the soil spatial distribution was recognized; then the experimental plots for monitoring the soil-plant water status were defined. Soil water variables (through TDR probes and tensiometers), crop development (biometric and physiological parameters) and climate variables (Temperature, radiation, rainfall, wind) were daily monitored. Afterwards, the model was calibrated and applied to estimate the crop water stress index. The results have been correlated to the crop physiological measurement (leaf gas exchange, chlorophyll-a fluorescence, leaf water potential, chlorophyll content, LAI measurement), grape bunches measurement (berry weight, sugar content, titrable acidity, etc.) and wine quality (aromatic response) in two different pedo-systems. Finally a preliminary "spatial application" of the model was carried out.

^[1]Shahrekord University ~ College of Agriculture ~ Shahrekord ~ Iran, Islamic Republic of ^[2]University of Lleida ~ Environment & Soil Science ~ Lleida ~ Spain

In this work, crop (vineyards) development measured by means of the Normalized Difference Vegetation Index (NDVI) from detailed remote sensing data area related to statistical significant differences of soil properties in different soil units (clusters). A detailed map of top soil properties of a 50-ha sample catchment was generated by means of digital soil mapping techniques, based on spatial interpolation methods and cluster analysis. The digital soil map was based on 40 soil samples distributed throughout the catchment. The NDVI was compute from bands 6 (red edge) and 5 (red) of the WorldView-2 satellite, with 2-m pixel resolution. The differences of the NDVI in each soil mapping unit were compared using ANOVA, which proved a significant difference of the NDVI in the soil map units ($\alpha = 0.001$). Different multiple range tests (LSD, Tukey and Duncan) were carried out to compare NDVI means in each soil map unit. The tests showed contradictory results, showing significant differences in some cases of clusters with different top soil properties and no significant differences of vine development in other cases of different top soil properties. The results are promising since they can validate the digital soil mapping process but point out the need of using additional soil properties such as soil depth or total available water retention capacity.

^[1]Natural Resources Canada ~ Canadian forest service ~ Québec ~ Canada ^[2]Université du Québec à Montréal ~ Centre d'étude de la forêt ~ Montreal ~ Canada ^[3]Lakehead University ~ department ~ Thunder Bay ~ Canada ^[4]agriculture et agroalimentaire Canada ~ department ~ Quebec ~ Canada ^[5]Université de Sherbrooke ~ biology ~ Sherbrooke ~ Canada

It is often assumed that litter palatability is the main factor driving changes in soil processes as the abundance of deciduous to coniferous trees changes in boreal forests. However, the transformation of the soil system is affected by numerous other processes. For example, the coniferous canopy cools the soil because of high light interception, it favours bryophyte communities that further cool the soil and make it wetter. These conditions make the soil environment inhospitable to certain groups of the meso- and macro-fauna. Finally, the vertical distribution of root systems, which vary with tree species, triggers different mechanisms of soil organic matter stabilization and de-stabilization. Field and laboratory studies were set-up to distinguish the relative contribution of these mechanisms. These included observations of element fluxes in situ in natural forests with different proportion of species, reciprocal exchanges of soils between forest types as well as laboratory microcosms study where the litter decomposition rate was measured for different combinations of litter type, litter mixture and soil provenance. Non-direct litter effects were found to be important. Because they vary with external conditions, their recognition when forecasting species effect in the context of a changing environment may be important. Important microclimatic effects and weak soil organic matter stabilization observed in coniferous stands suggest that the soil carbon storage of these stands is more vulnerable to environmental changes.

C AND N IN ABOVE- AND BELOWGROUND LITTER IN STANDS OF DIFFERENT TREE SPECIES IN NORTHERN FINLAND

Helmisaari Heljä-Sisko^{*[1]}, Sah Shambhu^[1], Smolander Aino^[2]

^[1]University of Helsinki ~ Dept. of Forest Sciences ~ Helsinki ~ Finland ^[2]Finnish Forest Research Institute ~ Vantaa Research Centre ~ Vantaa ~ Finland

*The aim of our study was to determine both above- and belowground tree litter production and C and N inputs to soil in silver birch, Scots pine and Norway spruce stands. We hypothesize that 1) C and N inputs in fine root litter may be larger than the corresponding inputs in foliage litter. 2) Fine root litter differs qualitatively from the foliage litter, e.g. the C:N ratio and the share of organic compounds may differ. We determined the litter production of fine roots and foliage in a tree species experiment in northern Finland in the 70-year old stands of silver birch (*Betula pendula* Roth.), Scots pine (*Pinus sylvestris* L.) and Norway spruce (*Picea abies* (L.) Karst.) growing on originally similar site type. The annual means of leaf/needle litterfall were 1810, 1970 and 1940 kg/ha in silver birch, Scots pine and Norway spruce stands, respectively. Respective annual N inputs in foliage litter were 19, 9 and 15 kg/ha. The annual fine root litter production and respective C and N inputs of birch were smaller but those of pine and spruce as large or larger than in needle litterfall. Fine roots, however, decomposed during the first two years more slowly than foliage. Spruce litter had the smallest mass loss, and birch litter the largest. The root longevity did not differ with soil depth. We conclude that both above- and belowground litter affect soil fertility and soil C under different tree species, and should be considered in ecosystem C and N budgeting.*

DYNAMICS OF SOIL CARBON, NITROGEN AND MICROBIAL BIOMASS DURING 20 YEARS OF SUCCESSION TOWARDS DECIDUOUS OR CONIFER CANOPY IN SUB BOREAL PLANTATIONS

Munson Alison^{*[1]}, Maillard Émilie^[1], Paré David^[2]

^[1]Université Laval ~ Centre d'étude de la forêt ~ Québec ~ Canada ^[2]Ressources Naturelles Canada ~ Service canadien des forêts ~ Québec ~ Canada

*Experimental conifer plantations established in 1986 in the sub-boreal region of Ontario, Canada, have evolved to contrasting canopy dominant species under different early silvicultural treatments. In those plantations treated with herbicide to control competing vegetation, the canopy is now dominated by the planted native pine (*Pinus strobus*) or spruce (*Picea glauca*), with a dominantly moss understory. Plantations that did not receive herbicide treatment essentially succeeded to native hardwoods (dominantly *Populus tremuloides* in the canopy) and a diverse shrub and herb understory, since mortality of planted conifers was almost 100%. We measured indicators of C and N cycles during the 20 year succession of these contrasting vegetation types, at 4, 10 and 20 years. Over this period we noted shifting ratios of total Corg:NT, Cmic:Corg, Nmic:Norg and Cmic:Nmic, in both the humus and superficial (0-10 cm) mineral horizons. NT gradually decreased in the humus over 20 years, however was consistently lower under the conifer canopy; at 20 years the Corg:NT was higher under the conifer (32) compared to the deciduous canopy (27). Nmic tended to be constantly lower under the conifer canopy at all sampling years, and at 20 years, Cmic:Nmic was higher under the conifer (6.2) compared to the deciduous canopy (5.0). In the mineral soil, Nmic was also lower and under the conifer canopy (all years), while Cmic decreased over 20 years, but only under the deciduous canopy. We discuss these results in relation to changing C and N cycles as well as potential external N inputs.*

*Different tree species differ in productivity, litter quality and quantity, canopy structure and nitrogen deposition. Norway spruce (*Picea abies*), Scots pine (*Pinus sylvestris*) and birch (*Betula pendula* and *B. pubescens*) are the three dominant tree species in Sweden. We compared soil C fluxes and the accumulation of soil organic carbon under adjacent Norway spruce, Scots pine and silver birch stands growing on similar soils and examined the different processes involved. This was achieved mainly through field measurements of carbon pools and fluxes in southern Sweden, combined with respiration and decomposition studies in the laboratory. Soil carbon fluxes and the accumulation of soil organic carbon were found to differ between the three species, with the strongest differences in humus layers between spruce and birch, with pine intermediate. Most carbon was stored in soils in spruce stands. Birch stands had the fastest root turnover and the highest carbon mineralisation rate. Species differences can be explained by differences in tree growth rate and litter decomposition. The three tree species differed in terms of litter quality, carbon mineralisation, DOC fluxes and fine root turnover.*

TREE SPECIES COMPOSITION CONTROLS SOIL C DYNAMICS IN MEDITERRANEAN MOUNTAINS FROM CENTRAL SPAIN

Díaz-Pinés Eugenio^{*[1]}, Montes Fernando^[2], Schindlbacher Andreas^[3], Dannenmann Michael^[1], Jandl Robert^[3], Rubio Agustín^[4]

^[1]Karlsruhe Institute of Technology ~ Institute for Meteorology and Climate Research. Atmospheric and Environmental Research ~ Garmisch-Partenkirchen ~ Germany ^[2]INIA ~ Centro de Investigaciones Forestales (CIFOR) ~ Madrid ~ Spain ^[3]Federal Research and Training Centre for Forests, Natural Hazards and Landscape ~ Directorate ~ Vienna ~ Austria ^[4]Universidad Politécnica de Madrid ~ Silviculture and Pasciculture ~ Madrid ~ Spain

Tree species composition influences the carbon cycle due to differential growth rates, quantity and quality of litterfall (both above- and belowground) and creation of different meteorological environments, among other factors. Therefore, soil C cycle is expected to vary depending on tree species composition, as well as soil C sequestration potential. Here, we present a synthesis work of tree species composition effects on soil C storage and C effluxes, focused on three ecotones between Scots pine and Pyrenean oak in Central Spain. The investigation of the stands showed a greater aboveground biomass in pine, as well as greater growth rates and, therefore, greater litterfall annual rates. Regarding soils (50 cm soil profile), pine stands stored a significant higher amount of OC than oak stands (95-140 vs. 45-70 Mg C ha⁻¹). However, differences in soil C stocks across vegetation types were mainly due to the particulate OC (> 53 µm) but not to the mineral-associated organic carbon (<53 µm). Soil lab incubations showed that the soil CO₂ efflux was much higher in soils from pine, but there were no differences neither in C decomposability, nor in temperature dependence of soil respiration, despite contrasting soil microbial communities (upon PLFA assessment technique). A precipitation simulation showed a similar response in relation to CO₂ emissions after rewetting irrespective to vegetation composition, but a huge N₂O pulse in soil from oak. We conclude that Scots pine is clearly preferable in terms of C sequestration than Pyrenean oak. References: Díaz-Pinés et al.2011. For Ecol Manag 262

NUTRIENT FLUXES AND SOIL MICROBIAL PROCESSES UNDER TREE SPECIES AFTER CONVERSION FROM NORWAY SPRUCE

Carnol Monique^[1], Bazgir Masoud^[2]

^[1]University of Liège ~ Biology, ecology, evolution/ Plant and microbial ecology ~ Liège ~ Belgium ^[2]Ilam University ~ Faculty of Agriculture, Water Resources Dep. ~ Ilam ~ Iran, Islamic Republic of

*The biogeochemical cycling in forest ecosystems is highly dependent on the interactions between plants and soil. Tree species affect element cycling through deposition in throughfall, litter composition, microbial activities in soil and rhizosphere processes. Species diversification has been suggested for maintaining forest ecosystem services and uniting provisioning and supporting services within multifunctional and sustainable forestry. However, most information on species impacts has been derived from studies performed at different sites, where the influence of cofactors cannot be accounted for. Here we synthesize results from a study performed 11 years after conversion of a Norway spruce stand (*Picea abies* (L.) KARST.) to a mixed stand composed of Norway spruce, common alder (*Alnus glutinosa* (L.) GAERTN.), european beech (*Fagus sylvatica* L.), pedunculate oak (*Quercus robur* L.), silver birch (*Betula pendula* ROTH.), goat willow (*Salix caprea* L.) and rowan (*Sorbus aucuparia* L.). As stand closure was not achieved yet, the impact of individual species could be evaluated. We measured fresh leaf element composition, element return to the soil via throughfall and litterfall (leaves, twigs, reproductive parts), forest floor chemical characteristics, microbial biomass and microbial activities (N mineralization, potential nitrification, respiration) in the forest floor under the different tree species. Our results suggested that (1) foliar element concentrations differed between species and were highest for rowan, (2) high base cation litterfall and throughfall fluxes under rowan lead to better soil quality, (3) input of acidifying cations was reduced under broadleaves, (4) potential nitrification increased under the N₂ fixing alder.*

Given current concerns about rising atmospheric CO₂ concentrations and their subsequent effects on global climate, it is of critical importance to identify the factors controlling soil organic C (SOC) storage. As the main C source in forest ecosystems, tree species have been shown to have an impact on the SOC accumulation rate and its vertical distribution within the soil profile. The need to evaluate the tree species impact on soil C stability is vital in informing forest planning and management strategies to maximize the long term C sequestration potential of European forests, however, the direct effect of tree species on C stabilization has not yet been reported. With the aim of understanding the tree species effect on SOC stabilization processes, chemical (water extractable and acid hydrolysable C) and physical (inter-/intra-aggregate light and organo-mineral C) fractionation schemes were applied to two contrasting soils (luvisol and podzol) where common-garden experiments (Sitka spruce, Douglas fir, Norway spruce, beech and oak) have been established since 1964 (Forest and Landscape Denmark). In addition, enzymatic assays (dehydrogenase, β -glucosidase, xylanase, phenol oxidase and peroxidase) were used to assess the tree species impact on C-related soil microbial activity. The results from this study will inform tree species selection in new afforestation projects that are already planned in most European Countries to mitigate climate change.

~ Cracow ~ Poland

The aim of the study is to evaluate differences occurring in the soil humus properties between two types of forests: natural beech forest and spruce monoculture. Dominance of spruce in lower forest belt of the Tatra Mountains is the effect of forest management in this area in the past. Large-scale plantations of Norway spruce had been established on large areas of beech sites till first decades of 20th century. The objects of investigation are two profiles representing Rendzic Leptosols under spruce and beech, and two profiles formed on allocthonous deposits on carbonate bedrock which can be classified as Rendzic Leptosol – under spruce forest and Haplic Cambisol – under beech site. The soil samples were analyzed for the basic properties as well as the fractional composition of humus fractions and particular analyzes of humus acids. Organic carbon content, pH, carbonates content and active carbonates content were measured. The composition of humus acids fractions and humification index were calculated after extraction and fractionation using Duchaufour and Jacquin method. Analyzes of C NMR and chemical composition of the humus acids were done. It is shown that different tree species strongly affect features of both ectohumus and endohumus horizons. It is visible in morphology of humus horizons as well as humus fraction composition and their properties. Another factor controlling features of humus horizons is parent material. It seems to be possible to separate effects which are results of vegetation and parent material features.

*Tree species produce leaf litter with different chemical composition and degradability, and these differences might influence the composition and reactivity of the soil solution. Moreover, tree species that accumulate trace metals in their foliage, might show retarded leaf litter decomposition. The soil solution composition in turn affects the behaviour and mobility of trace metals within the soil profile. Hence, tree species choice has a meaningful influence on metal mobility in ecosystems, which emphasizes the importance of tree species selection with respect to risk control. We studied the biogeochemical effects of leaf litter decomposition on the soil solution by sampling leaf litter leachates with zero-tension lysimeters. We selected six tree species in a forest on a metal contaminated site (*Populus tremula*, *Betula pendula*, *Robinia pseudoacacia*, *Quercus* spp., *Pinus sylvestris*, *Pseudotsuga menziesii*). Apart from the characterization of the leaf litter leachates generated from in situ (contaminated) litter, not-contaminated leaf litter from the six considered tree species was brought to the study site as well. We will present our results of the tree species effects on leaf litter leachates, considering contaminated versus not-contaminated leaf litter, allowing to gain fundamental insights in the driving factors of terrestrial metal cycling.*

A change in land use from agriculture to forest generally increases soil acidity. However, it remains unclear to what extent plant traits can enhance or mitigate soil acidification caused by atmospheric deposition. An in-depth understanding of tree species-specific effects on soil acidification is crucial for soil protection, particularly in view of the predicted global increases in acidifying nitrogen (N) deposition. We report soil acidification rates in a chronosequence of broadleaved deciduous forests planted on former arable land in Belgium. This region receives one of the highest loads of potentially acidifying atmospheric deposition in Europe, which allowed us to study a 'worst case scenario'. We show that less than four decades of forest development caused significant soil acidification. Atmospheric deposition drives post-agricultural forests towards more acidic conditions, but the rate of soil acidification is also determined by the tree species-specific leaf litter quality and litter decomposition rates. We propose that the intrinsic differences in leaf litter quality among tree species create fundamentally different nutrient cycles within the ecosystem, directly through the chemical composition of the litter and indirectly through its effects on the size and composition of earthworm communities. Poor leaf litter quality contributes to the absence of a burrowing earthworm community, which retards leaf litter decomposition and results in forest-floor build-up and soil acidification. Also nutrient uptake and N₂ fixation are causing soil acidification, but were found to be less important. Our results highlight the fact that tree species-specific traits significantly influence the magnitude of human pollution-induced soil acidification.

S10.03b -5

CHANGES OF SOIL CHEMISTRY, WATER AND NUTRIENT FLUXES IN GERMAN FORESTS AFTER REPLACEMENT OF NORWAY SPRUCE WITH DOUGLAS FIR COMPARED TO EUROPEAN BEECH

Prietzl Jörg^[1], Sven Bachmann^[1]

^[1]Technische Universität München ~ Ecology and Ecosystem Management ~ Freising-Weihenstephan ~ Germany

*Of the main commercial tree species in Germany, Norway spruce (*Picea abies*) is supposed to be most negatively affected by the expected climate change. European beech (*Fagus sylvatica*) and Douglas fir (*Pseudotsuga menziesii*) are considered less vulnerable; moreover, the growth potential of Douglas fir exceeds that of spruce. Thus, current forest policy and management aims to reduce the percentage of Norway spruce monocultures and to increase the percentages of Douglas fir and European beech in German forests. In our study, effects of a tree species change from Norway spruce to Douglas fir and European beech on soil chemistry, and ecosystem water and nutrient fluxes were investigated in 19 (soil) and 5 (water and nutrient fluxes) forest stands on different sites. Replacement of Norway spruce by Douglas fir or European beech resulted in decreased topsoil acidity as well as in thinner forest floor layers with more active humus forms, decreased C/N ratios, and decreased organic carbon (OC) stocks. All effects were more pronounced under European beech compared to Douglas fir. Total soil OC losses after replacement of spruce by Douglas fir (on average -7%) and European beech (on average -11%) increased with stand age. Compared to Norway spruce at the same site, seepage water fluxes were decreased under Douglas fir, and increased under European beech. At sites with increased N saturation, replacement of spruce by beech resulted in a strong decrease in seepage water NO₃-concentration, whereas no decrease or even increases were observed after replacement of spruce by Douglas fir.*

DETERMINATION OF PLANT-AVAILABLE PHOSPHORUS FORMS IN SOIL UNDER CONSIDERATION OF THE INFLUENCE OF DIFFERENT TREE SPECIES

Niederberger Jörg^[1], Bauhus Jürgen^[1], Kohler Martin^[1]

^[1]University of Freiburg ~ Institute of Silviculture ~ Freiburg ~ Germany

The results of the first German nationwide forest soil survey suggested a limited P supply for nearly 60 % of the German forest sites. However, there was no correlation between the foliar P concentrations and the total P content in soil, suggesting that total soil P is not a good indicator of P available to trees. Yet, to assess soil fertility and for example management options to utilize additional forest biomass, efficient methods are needed to determine P availability in forest soils. Here we used the Hedley fractionation method to determine the different forms of available P in a subset of samples from 62 spruce and 26 beech sites from the nationwide forest soil survey. All in all, six inorganic and four organic P forms, as well as the residual P content, were measured. However, because this sequential extraction methods is very labour-intensive, we assessed whether proxies may be measured for the soil P fractions. Therefore, in a second stage, we tested whether Hedley P fractions could be determined by means of an indirect and more inexpensive technique; the Near Infrared Spectroscopy (NIRS). First results indicate considerable differentiation in the P distribution among the various fractions for spruce and beech. The content of labile organic P, for instance, was clearly higher for spruce sites in comparison to beech sites. In contrast the content of HCl soluble P was higher for Beech sites than for Spruce sites.

THE EFFECT OF DOMINANT TREE SPECIES ON SOIL MICROBIAL COMMUNITY, SOIL FAUNA AND CARBON STORAGE

Frouz Jan*^[1]

^[1] Faculty of sciences, Charles University ~ Institute for Environmental studies ~ Prague ~ Czech Republic

Carbon storage in aboveground tree biomass and soil organic matter (fermentation and humus layer), microbial respiration and biomass, and in situ litter decomposition was studied in post mining sites in northwest of the Czech Republic covered by seven various types of forests: alder, lime, oak, larch, pine and spruce plantations, and unreclaimed sites dominated by aspen, birch and willow. No topsoil was applied in these sites, so carbon accumulation is was the result of in situ soil development. Carbon storage in soil organic matter varied from 4.5 ± 3.7 to 38.0 ± 7.1 $t\ ha^{-1}$ (rate of C accumulation 0.15 ± 0.05 to 1.28 ± 0.34 $t\ ha^{-1} year^{-1}$). It decreased in order: lime, alder, larch, oak, pine, spruce and unreclaimed natural regeneration sites. No correlation was found between litter input and C storage in soil. There positive correlation with litter decomposition rate and carbon storage. These were no correlation between C storage in soil and soil respiration or microbial biomass. Amount of carbon in mineral layer and total soil carbon also correlated positively with earthworm abundance and amount of earthworm casts in profile. Field and laboratory manipulation experiment support the hypothesis about significant effect of soil fauna bioturbation on carbon storage. Laboratory experiment shows that incorporation of litter in soil by earthworms result in stronger carbon storage than mechanical mixing of soil or no mixing. Results indicate that soil fauna development play important role in soil formation in post mining sites.

MICROBIAL COMMUNITIES IN ASPEN- AND SPRUCE FOREST FLOORS OF THE BOREAL MIXEDWOOD

Quideau Sylvie^[1], Kishchuk Barbara^[2], Swallow Mathew^[1], Lloret Emily^[1]

^[1]University of Alberta ~ Renewable Resources ~ Edmonton ~ Canada ^[2]Natural Resources Canada ~ Canadian Forest Service ~ Edmonton ~ Canada

The boreal mixedwood forest of western Canada is composed of a mosaic of forest types, ranging from aspen-dominated to spruce-dominated stands. Soil microbial communities, and how they respond to disturbance, are a key component of site productivity through their regulation of organic matter and nutrient cycling patterns. Phospholipid fatty acid and substrate-induced respiration analyses were used to compare the microbial biomass and microbial community structure of forest floors as a function of disturbance (harvesting, silvicultural burning) and stand type (aspen, spruce, mixedwood). Distinct differences were found among stand types using both techniques, which seemed to be strongly affected by the presence of white spruce and the composition of the understory vegetation. On the other hand, differences among stand types appeared resilient to both harvesting disturbance and silvicultural burning. Microbial community stability was maintained even when the belowground (root) and surficial litterfall inputs were manipulated during a reciprocal transfer experiment. Furthermore, laboratory incubations using ¹³C- enriched substrates as well as a moisture manipulation experiment indicated that the communities differed in their ability to metabolize substrates. Microbial community stability in the white spruce forest floor appeared to be minimally impacted by lowering moisture. Yet moisture had a profound effect on the aspen forest floor, which harbored structurally and functionally distinct microbial communities at different moisture levels. The distinct response to moisture manipulation in aspen and spruce could be a result of community adaptations to the unique abiotic environment inherent to each forest floor.

*Tree species can influence the properties of forest soils by differences in litter quality, microclimate, nutrient uptake, interception of atmospheric deposition, biological soil community and soil nutrient transformation rates. Diverging soil conditions under different tree species are well known but have rarely been related to possible differences in microbial communities. Therefore, the aim of our study was to characterize the structure of the active microbial community in the soil beneath two contrasting tree species (*Quercus robur* L. and *Pinus sylvestris* L.). The experiment was performed in two pairs of adjacent equal-aged deciduous and coniferous stands growing on a well-drained sandy soil with similar stand history, located in a region with enhanced nitrogen deposition (Belgium). In the four study stands the mineral topsoil (0-10 cm) was injected with an amino acid (glycine) that was enriched in the heavy stable carbon (C) isotope. Soils were sampled 1 and 7 d after injection in order to assess the structure of the active soil microbial community. The relative importance of living functional soil microbial groups (gram-positive and gram-negative bacteria, saprophytic fungi, arbuscular mycorrhizal fungi and actinomycetes) was determined by analyzing phospholipid fatty acids (PLFAs). Determining the ¹³C content of PLFAs also allowed quantifying the microbial groups that actively assimilated the applied glycine, in contrast to more common PLFA studies that only fingerprint the living microbial groups. The results will be discussed in relation to our earlier findings on biogeochemical processes, particularly of nitrogen, in the studied forest stands.*

S10.03c -4

EFFECTS OF CHANGES IN TREE SPECIES, LAND-USE CHANGE, AND CLIMATE CHANGE ON FOREST NITROGEN RETENTION AND LOSS.

Templer Pamela*^[1]

^[1]Boston University ~ Biology ~ Boston ~ United States

Forests of the northeastern United States receive some of the highest rates of atmospheric nitrogen deposition and many watersheds are beginning to show signs of nitrogen saturation. In addition to changes in atmospheric deposition of nitrogen, other human-induced disturbances have led to dramatic shifts in forest composition of the United States over the last 100 years. Tree species composition of many forests is changing in response to introduced pests and pathogens, land-use change, and climate change. Understanding the combined effects of increased nitrogen inputs and changes in plant species composition on forest nitrogen cycling is critical to our understanding of forest biogeochemistry and nutrient budgets. Despite several decades of research on the effects of atmospheric nitrogen deposition, there is still significant uncertainty about the factors that regulate nitrogen retention and loss in forest ecosystems. We used a combination of enriched isotopic tracers (to follow specific cohorts of nitrogen inputs) and evaluation of natural abundance nitrogen and oxygen stable isotopes of nitrate (to determine sources of nitrate leached from forests). We evaluated the combined impacts of changes in tree species composition, land-use change, and climate change on nitrogen retention and loss in northern hardwood forests. Results from these studies suggest that tree species composition can be a strong regulator of forest nitrogen retention, but differences among species may change depending upon nitrogen inputs, previous land-use change, and projected changes in climate.

S10.03c -5

TREE SPECIES EFFECTS ON THE MYCORRHIZAL CO₂ FLUX

Menyailo Oleg*^[1]

^[1]Institute of Forest SB RAS ~ Biogeochemistry ~ Krasnoyarsk ~ Russian Federation ^[2]University of York ~ Biology ~ York ~ United Kingdom

Mycorrhiza plays an important role in global carbon cycle, especially, in forest soils, yet the effect of tree species on the amount and timing of C transfer through roots to mycorrhiza is largely unknown. We studied the C transport to mycorrhiza under 6 most commonly dominant in boreal forests tree species using the Siberian afforestation experiment. The CO₂ flux from mycorrhizal and non-mycorrhizal mesh collars was measured every two weeks from May until October of 2010 and 2011. The two years were different in time of snow melt, summer precipitation allowing assessing the role of mycorrhiza in inter-annual variability in CO₂ flux. During the overall dry summer of 2010, the difference in soil surface CO₂ flux between the tree species were determined mostly by difference in mycorrhizal flux, while during the wetter summer of 2011, soil heterotrophs also contributed to the difference in CO₂ flux between the tree species. The mycorrhizal CO₂ flux was not linked to soil temperature but rather to trees phenology and to photosynthetic activity. All tree species transferred more carbon to mycorrhiza during the second half of summer and in September, this is because all the carbon photosynthesized earlier is used for building the trees biomass. Seasonal variation in C transfer to mycorrhiza was much larger than hourly variation (within a day). Tree species strongly differed in C flux to mycorrhiza: more C was transferred by deciduous species than by conifers.

RELATIONSHIPS BETWEEN TREE SPECIES AND CURRENT PEDOGENETIC PROCESSES

Legout Arnaud^[1], Jaffrain Jérôme^[1], Titeux Hugues^[2], Zeller Bernhard^[1], Ranger Jacques^[1]

^[1]INRA ~ Biogéochimie des Ecosystèmes Forestiers ~ Champenoux ~ France ^[2]University of Louvain ~ Earth and Life Insitue Environmental sciences -Soil science ~ Louvain la Neuve ~ Belgium

According to global change, tree species composition will change, to more diverse stands or to highly productive monocultures. Both options will impact the current ecosystems functions. A study held in a common garden experiment set on acid soils (Morvan France) gave new insights in the impact of tree species on forest soil functions: -Net mineralization and principally nitrification depends on vegetation. Stimulation of nitrification occurred in Douglas fir, pine, beech and oak, reduction in spruce, fir and in the former broadleaved forest. - The soil solutions used as indicators showed strong species effects: o the forest-floor solutions were species dependent: DOC controlled the transfer of Al under spruce but nitrate did it under Douglas fir. o Solutions in the mineral soil revealed very different figures. Transfer of nutrient cations due to proton neutralisation, and of monomeric Al associated with excess nitrate dominated under pine, Douglas fir and secondarily under oak and spruce, while, transfert of organically bound Al and Fe dominated under broadleaved trees and fir. o Solution from limed coniferous stands showed a strong decrease in NO₃⁻ and Al. Calcium changes only occurred just below the forest soil, indicating a very conservative biological recycling of this element. Tree species oriented current soil processes: acidification by species which stimulated nitrification in a system unable to immobilize nitrates (case of Douglas fir and laricio pine), complexation by DOC under spruce or fir. Liming efficiently mitigated the deleterious effects of excess nitrification, avoiding transfer of Al towards the deep soil layers.

Soils contain two to three times more carbon than the atmosphere or terrestrial vegetation. Therefore, slight changes in the rate of soil organic carbon (SOM) decomposition can significantly affect the atmosphere CO₂ concentration. The temperature sensitivity of decomposition of different SOM fractions was studied by using ¹³C and ¹⁴C isotopes to differentiate between SOM of different age. The quality of SOM and the functionality and composition of microbial communities formed under different climatic conditions were also studied. Transferring of soils from a colder to a warmer climate was used to assess how changing climate, litter input and soil biology will affect soil respiration and its temperature sensitivity. Our studies show how warming climate will affect the decomposition of different SOM fractions in boreal soils: the most labile C was least temperature sensitive, indicating that it is utilized irrespective of temperature. The decomposition of intermediate C was highly temperature sensitive. Oldest, centennially cycling C was again less temperature sensitive, indicating that different stabilizing mechanisms were limiting its decomposition. Because the highly temperature sensitive C forms a major part of SOM in the studied soils, these soils will lose more carbon in future than estimated earlier. SOM decomposition in boreal soils will increase more in response to warming, compared to temperate or tropical soils, also because the Q₁₀ is temperature dependent. In the northern soils the warming will occur within a lower temperature range, where Q₁₀ is higher, and a similar increase in temperature causes a higher relative increase in respiration rates.

The impact of climate change on the stability of soil organic carbon (SOC) remains a major source of uncertainty in predicting future changes in atmospheric CO₂ levels. The sensitivity of SOC mineralization to global warming remains unsettled, with one particular issue being whether the mineralization response to temperature is the same for labile and stable SOC pools. Long-term (>25 years) bare fallow experiments (LTBF) in which the soil is kept free of any vegetation, represent a unique research platform to examine this issue as with increasing duration of the treatment, the proportion of stable SOC increases. This study employs soils from LTBF experiments situated at Askov (Denmark), Grignon (France), Versailles (France) and Ultuna (Sweden). We used archived soils sampled at the start of the experiments and after 25, 50, 80 and 52 years of bare fallow, respectively, when the soils had become enriched in stable SOC. The samples were incubated at one fixed water potential (-0.32 bars) and four different temperatures (4, 12, 30 and 35 °C). The evolution of total CO₂ and of ¹³CO₂ from the incubated soils was monitored for one year. The results indicate a higher vulnerability of SOC in LTBF soils enriched in stable C. However, we observed no relationship between the duration of the bare-fallow treatment and the temperature sensitivity of SOC. Interestingly, the quality (as determined by δ¹³C) of the mineralized SOC depended on the incubation temperature. Further modelling will allow us to determine the temperature sensitivity of kinetic pools in SOC simulation models.

Litter decomposition represents one of the largest fluxes in the global terrestrial carbon cycle. It is therefore crucial to better understand the factors governing decomposition and their responses to changing environmental conditions. We used high-to-low elevation soil translocation to simulate the combined effects of changing climatic conditions, shifting vegetation zones and altered snow cover regimes in the Austrian Limestone Alps. Over a two-year incubation period, we studied carbon turnover dynamics and pathways of carbon during microbial decomposition of isotopically labeled maize straw. A simulated mean annual soil warming of 1.5 and 2.7°C, respectively, resulted in a significantly accelerated turnover of added maize carbon at the lower elevation sites. The more resistant carbon pool (half-life: 1-2 years) responded more strongly to experimental warming (100-190% increase in decomposition rate) compared to the labile pool (half-life: 1-2 weeks; 5-20% increase in decomposition rate). Changes in substrate quantity and quality in the course of the decomposition appeared to have less influence on the microbial community composition and its substrate utilization than the prevailing environmental conditions, to which the microbial community adapted quickly upon change. In general, microbial community composition and function significantly affected substrate decomposition rates only in the later stage of decomposition when the differentiation in substrate use among the microbial groups became more evident. Our study demonstrates that rising temperatures in alpine ecosystems will accelerate decomposition of litter carbon, especially in more resistant pools, but also lead to a rapid adaptation of the microbial communities to the new environmental conditions.

UNCERTAINTIES OF MODELING ECOSYSTEM RESPIRATION BASED ON SOIL TEMPERATURE – CAN THEY BE REDUCED USING MANUAL AND AUTOMATIC CHAMBER MEASUREMENTS?

Hagemann Ulrike^[1], Madlen Pohl^[1], Jürgen Augustin^[1]

^[1]Leibniz-Centre for Agricultural Landscape Research (ZALF) e.V. ~ Institute of Landscape Matter Dynamics ~ Müncheberg ~ Germany

A common method for estimating ecosystem respiration (Reco) relies on periodic daytime measurement campaigns using a non-flow-through non-steady-state opaque chamber system (Livingston and Hutchinson 1995) with continuous sampling (Drösler 2005). Gaps between measurement campaigns are filled by modeling Reco based on continuously logged soil temperatures using the Lloyd-Taylor model (Lloyd and Taylor 1994). This method relies on the assumption that nighttime Reco fluxes can be modeled based on measured daytime fluxes. To test this assumption and facilitate gap-filling, we have made comparative measurements near the manual measurement locations using a high-resolution automatic chamber system. Results show that the Lloyd-Taylor model parameters based on manually measured daytime Reco fluxes differed from those based on automatically measured nighttime fluxes, resulting in higher values of nighttime Reco based on daytime measurements compared to nighttime measurements. As the annual soil carbon budget of agricultural areas often fluctuates around zero (Kutsch et al. 2010), this difference may have serious implications with respect to annual estimates of Reco and determine the evaluation of the carbon source or sink functionality of these sites. We discuss possible reasons for the differences between manual daytime and automatic nighttime chamber measurements, in particular a) chamber construction, b) small-scale spatial variability of Reco, c) wind turbulence and layering effects, d) plant physiology, and e) the applicability of the Lloyd-Taylor model, and explore the effect of Reco modeling based on manual and/or automatic measurements on the annual GHG balance of corn (*Zea mays* L.) in a young moraine landscape of north-eastern Germany.

IMPROVEMENT OF ENGINEERING PROPERTIES OF SOILS WITH BIOPOLYMER ADDITIVES

Yukselen-Aksoy Yeliz*^[1], Ayhan Anil^[1]

^[1]Celal Bayar University ~ Civil Engineering ~ Manisa ~ Turkey

In the literature, the recent studies have shown that the rate use of biopolymers in geotechnical engineering increases in recent years. The xanthan gum and chitosan biopolymers are economical polymers, have been extensively used in industry and available in the nature. Therefore, these two biopolymers were selected for this study. In this study, the consistency limits, swell indexes, consolidation parameters and permeability of the samples which were prepared different concentrations of biopolymers were investigated. In general results show that, the liquid limit values of kaolin and bentonit samples increased with used biopolymer additives. The effects of biopolymers were distinctly seen on bentonite, because its higher liquid limit value than kaolin. In the presence of xanthan gum and chitosan biopolymers, increase in plastic limit values of bentonite sample distinctly higher than the kaolin sample. In the presence of of xanthan gum biopolymer, only the modified free swelling index of kaolin decreased. However, the modified free swell indexes of the kaolin and bentonite samples decreased in the presence of chitosan. According to these results, it was concluded that chitosan can be used for decreasing of swelling potentials of soils which have high swelling potential. The consolidation coefficients decreased when xanthan gum concentration increases under the same load. General results have shown that biopolymers can be used in geotechnical engineering for special purposes.

Recent studies have produced conflicting results in terms of the effects of long-term temperature changes on the functioning of soil microbial communities. We are investigating whether adaptation of soil microbial communities to temperature generally enhances (enhancement) or reduces (thermal acclimation) the direct effects of temperature changes on decomposition rates. Previously, we developed a soil-cooling approach which involves cooling samples after respiration rates have stabilised following a prolonged pre-incubation period, and determining the potential for respiration rates to recover during extended exposure to lower temperatures. In contrast to other studies, our initial research demonstrated enhancement in Arctic soils. Here we present results from a new project which is extending the approach to temperate, Mediterranean and tropical soils. We also aim to disentangle the mechanisms behind any observed responses by characterising the composition and function of microbial communities in the cooled and control soils; microbial biomass, PLFAs, mass-specific activity, carbon-use efficiency, and the activities of enzymes involved in the break-down of labile versus more recalcitrant compounds, are all being quantified. Initial results from temperate soils generally show no clear signs of thermal acclimation, but responses were dependent on soil type and the temperature range investigated; at low temperatures further evidence for enhancement was produced. Incubation of Mediterranean and tropical soil samples is ongoing and will be completed by March, allowing responses at high soil temperatures to be elucidated. The study represents one of the most extensive investigations undertaken to date into the potential for thermal acclimation under contrasting environmental conditions.

TEMPERATURE EFFECTS ON BACTERIAL GROWTH IN SOIL AFTER NUTRIENT ADDITION, DRYING/REWETTING AND FREEZING/THAWING.

Baath Erland*^[1]

^[1]Lund University ~ Microbial Ecology, Dep Biology ~ Lund ~ Sweden

Temperature has a direct effect on bacterial growth rates in soil, usually following a square-root relationship below optimum temperature, with Q10 decreasing with temperature. Temperature will, however, also affect the rate with which the bacteria will react on environmental perturbations. Adding substrate (glucose) to soil results in a lag-period before bacterial growth, measured with the leucine incorporation method, increases above that in the control soil. The lag period scaled with temperature, increasing from less than 10 h at 25-30°C, to around 2 days at 5°C, and > 5 days at 0°C. A similar temperature effect was found for the bacterial growth recovery after a drying/rewetting event. Bacterial growth increased linearly with time after rewetting, reaching the level found in a constantly moist control soil after less than 10 h at 25°C, after around 3 days at 15°C and after around 10 days at 5°C. Bacterial growth after freezing/thawing also appeared to increase linearly with time, reaching levels in a non-frozen control soil after around 2 days at 5°C. The freezing temperature affected the recovery. A temperature of -18°C resulted in lower initial growth rates after thawing, but eventually in higher growth compared to a freezing temperature of -3°C. Having in mind that one of the predicted effects of global change will be more perturbation events like drying/rewetting and freezing/thawing, the effect of temperature on the microbial response to such perturbations should be evaluated.

TEMPERATURE SENSITIVITY OF ENZYMES ACTIVITY IN SOIL AS DEPENDENT ON SUBSTRATE AMOUNT AND DROUGHT EFFECT

Blagodatskaya Evgenia*^[1], Schrumpf Marion^[2], Weber Enrico^[2], Wutzler Thomas^[2], Reichstein Markus^[2], Trumbore Susane^[2]

^[1]Institute of Physicochemical and Biological Problems in Soil Science Russian Academy of Sciences ~ Russian Academy of Sciences ~ Pushchino ~ Russian Federation ^[2]Max Planck Institute for Biogeochemistry ~ Biogeochemical Processes ~ Jena ~ Germany

The decomposition of soil organic matter (SOM) is mediated by the activity of extracellular enzymes, which, in turn, is dependent both on the amount and availability of decomposed substrates. According to Michaelis-Menten relationship, the different drivers are responsible for the temperature sensitivity of SOM decomposition at low (K_m) and high (V_{max}) substrate amounts. We tested the temperature sensitivity of the K_m and V_{max} for the set of 6 hydrolytic enzymes responsible for the different stages of decomposition of soil organics (such as starch, cellulose, hemicellulose, chitin etc.) as well as for the enzymes degrading the aromatic compounds (peroxidases and phenoloxidases). Enzyme kinetics was determined in the course of QuaSOM experiment (Max Planck Institute for Biogeochemistry Jena, Germany) where continuous ^{13}C - CO_2 -labeling was applied during vegetation of peppermint (*Mentha piperita* L.) under deficit and optimal moisture regimes. Our study revealed the group of the enzymes (α -glucosidase, xylanase, chitinase) with multiphase Michaelis-Menten kinetics. The temperature sensitivity of the enzymes activity decreased with the increasing substrate concentrations. Contrasting responses of phenol- versus peroxidases to different moisture regimes were most pronounced in the rhizosphere of peppermint. The drought effect on the enzymes activity will be linked with the partitioning of plant-originated and SOM-originated carbon in heterotrophic respiration and in microbial biomass. A mechanism of microbial adaptation to the periodical draughts consisted in much larger increase in K_m than in V_{max} as a response to increasing temperature.

S11.01b -3

SEASONAL VARIATIONS IN THE AVAILABILITY OF LABILE SUBSTRATE CONFOUND THE TEMPERATURE SENSITIVITY OF HETEROTROPHIC RESPIRATION.

Kirschbaum Miko*^[1]

^[1]Landcare Research ~ Global Change Processes ~ Palmerston North ~ New Zealand

In deriving the temperature dependence of heterotrophic respiration from empirical observations, changing substrate availability can confound any inferred inherent temperature sensitivity. This is a potential problem under any experimental or observational setting. Its potential effect for measurements under seasonally varying temperatures is investigated here in a modelling study. The CenW/ CENTURY model was run with different lignin to nitrogen ratios of fresh litter, and with litter either becoming available continuously or with litter production being restricted to autumn leaf fall. It was investigated to what extent inclusion of varying substrate supply within a realistic modelling framework modified the derived temperature sensitivity of heterotrophic respiration. It was shown that in systems with recalcitrant litter, as might be produced by conifers or eucalypts, the confounding effect of changing substrate supply is only slight. In systems with more labile litter, however, such as that produced by nutrient-rich grasslands, the confounding effect of substrate availability can be important and can substantially weaken any derived temperature sensitivity. This effect is even more pronounced in systems where litter fall is restricted to the autumn months.

S11.01b -4

ANNUAL VARIATION IN CO₂ EFFLUXES IN AFFORESTED AND AGRICULTURAL SOILS

Zorita Félix^[1], Trasar-Cepeda Carmen^[2], Leirós M. Carmen^[2], Gil-Sotres Fernando^[2]

^[1]IIAG-CSIC ~ Bioquímica del Suelo ~ Santiago de Compostela ~ Spain ^[2]USC ~ Edafología y Química Agrícola ~ Santiago de Compostela ~ Spain

In the 1990s, the European Union subsidised the afforestation of agricultural land as a means of mitigating climate change. This policy was based on the idea that afforestation would lead to accumulation of organic carbon in plant biomass and soils, thus contributing to the removal of atmospheric CO₂ (the main greenhouse gas) via the action of the soil as a C sink. As a result, large areas of agricultural land (not only marginal but good quality land) were transformed into forest land. However, the effectiveness of the policy has still not been demonstrated. In the present study, we investigated how the afforestation of agricultural soils (maize cropped soils) affects soil CO₂ effluxes. For this purpose, the daily variations in the CO₂ effluxes were monitored in forest soils and in the agricultural soils from which they were derived. The CO₂ effluxes were measured monthly in winter, and fortnightly during the rest of the year, using a portable Infra Red Gas Analyzer and a closed soil chamber. The results showed that there were no clear differences between the afforested and cropped soils, as the only time that significant differences were observed were when agricultural activities were being carried out. It was also found that when water was not limited, the CO₂ effluxes were closely related to temperature, so that the maximum emissions occurred at midday.

S11.01b -5

CARBON CONTROLS ON SOIL RESPIRATION ACROSS A TROPICAL ELEVATION GRADIENT: EVIDENCE FROM THE ANDES

Whitaker Jeanette^[1], Meir Patrick^[2], Mcnamara Niall^[1], Ostle Nick^[1], Bardgett Richard^[3]

^[1]Centre for Ecology and Hydrology ~ Shore Section ~ Lancaster ~ United Kingdom ^[2]University of Edinburgh ~ Centre for Environmental Change & Sustainability ~ Edinburgh ~ United Kingdom ^[3]Lancaster University ~ Lancaster Environment Centre ~ Lancaster ~ United Kingdom

The Tropical Andes is predicted to warm by 3-5 °C this century with unknown feedbacks to ecosystem processes. There is concern that climate change could result in significant losses of carbon from these soils through temperature driven increases in soil respiration. However, the climatic vulnerability of these large soil carbon stores is poorly understood. In this project we investigated the role of soil biological and physical properties in determining soil respiration along an elevation gradient from 200 m to 3700 m asl. With soils sampled from 14 locations along the gradient we examined variation in soil and microbial biomass C and N, and microbial diversity (using phospholipid fatty acid biomarkers). A series of carbon substrate addition experiments were conducted to determine the role of carbon quality and quantity in constraining soil respiration, using substrates of increasing complexity (from glucose to hemicellulose). Results show that soil C and N content, microbial biomass C and N and total microbial biomass all increase with altitude, with a significant decrease in soil bacterial:fungal ratios. Experimental results reveal that (a) carbon quality and quantity constrain soil respiration across the elevation gradient; and (b) soils capacity to utilise carbon substrates is strongly correlated with soil and microbial C content and microbial biomass. The implication of this work is that soil biological and chemical properties will be important determinants of CO₂ feedbacks to the atmosphere in this region as climate change progresses.

INDICATION OF SOIL AMINO SUGARS TO WARMING EFFECT ON MICROBIAL TRANSFORMATION PROCESS OF SOM IN A TEMPERATE STEPPE

Zhang Xudong^{*[1]}, He Hongbo^[1], Wang Yang^[1]

^[1]Institute of Applied Ecology, Chinese Academy of Sciences ~ State Key Laboratory of Forest and Soil Ecology ~ Shenyang ~ China

The unprecedented global warming can profoundly impact SOC cycling, but how the warming impact is attributed to the microbial transformation process of SOM is unclear. As reliable microbial residue biomarkers, amino sugars are usually used to elucidate microbial processes of C dynamics, as they are highly involved in microorganism-mediated SOC cycling. Here we present results from a 3-year field experiment to investigate the effect of asymmetric diurnal warming (control, day warming, night warming and diurnal warming) on soil amino sugar signatures and aimed to evaluate the indicative role of amino sugars to warming effect on the microbial transformation process of SOM in a temperate steppe of northern China. Our results indicated that the three warming treatments affected soil amino sugar signatures differently, i.e. fungal- and bacterial-derived residues indicated different responses of microbial communities to asymmetric diurnal warming. Interestingly, day warming had no significant effect on both bacterial muramic acid and fungal glucosamine, while night warming increased the concentrations of both amino sugars significantly. Although diurnal warming did not show any interactive effect on the two microbial residues, amino sugar concentrations were still higher compared to the control and day warming treatments. On the base of fungal to bacterial residue ratios and the proportion of microbial residue carbon to SOC, we concluded that night warming can enhance the accumulation of fungal residues and stability of soil organic matter, while day warming will resulted in more rapid transformation of soil organic matter and possible organic carbon loss in the steppe soil.

Soils provide essential ecosystem services such as primary production, regulation of biogeochemical cycles and their consequences on climate, water filtration, resistance to pests and diseases, and regulation of above-ground biodiversity. These services result from functions supported by soil organisms. Their abundance, diversity and activities vary according to environmental factors and Human activities. Despite progress made over the last decade in assessing soil biodiversity, the huge reservoir of biodiversity represented by soils remains superficially explored as do the relations between soil biodiversity and functioning. This lack of knowledge is related to the small size of most organisms, their hidden location, the matrix structure of the soil and the immense variety of environmental conditions. Knowing the range of biodiversity, its contribution to soil functioning and ecosystem services, and the impact of the variety of environmental situations on both parameters is thus a critical challenge to be addressed. This knowledge is required by the European Commission for defining a policy for sustainable management of soils with a view to adopt a legally binding Soil Framework Directive. Case studies on C and N cycling will be presented to illustrate the connection between soil biodiversity and functions. Also, data demonstrating the contribution of environmental filters as drivers of microbial communities will be shown. Finally, a brief overview of the EU FP7 EcoFINDERS will show how it can provide the EC with scientific, operational and economic information on biodiversity to design and implement strategies for ensuring sustainable use of soils.

ECOSYSTEM SERVICES PROVIDED BY THE SOIL BIOTA

Brussaard Lijbert*^[1], Faber Jack H.^[2]

^[1]Wageningen University ~ Soil Quality ~ Wageningen ~ Netherlands ^[2]Alterra ~ Moleculair Ecology, Ecotoxicology and Wildlife Management ~ Wageningen ~ Netherlands

We connect the soil biota to ecosystem structure and functioning and the concept of ecosystem services, i.e. the benefits people derive from ecosystems, and to the impact of land management and environmental drivers of change upon such phenomena. Following recent developments in trait-based ecology, functional trait groups, based on organismal- and species- trait diversity, addressing multiple associations between traits and ecosystem services across different trophic levels, are proposed as more suitable than functional groups based on species diversity per se, in relating drivers of change to soil biota-mediated ecosystem functioning and services. The concept of functional trait groups will be presented as useful when we wish to extend basic understanding of ecosystem functioning to practical management for enhanced ecosystem services. From a set of studies we infer that judicious choices of tillage systems and crops/cultivars in arable agriculture, animals in livestock husbandry and grazing systems, and crops and animals in mixed farming, optimize the delivery of ecosystem goods and services and, hence, make agricultural production systems both more efficient and more robust, i.e. adaptable to changing climate variability and environmental and economic risks. The evidence, limited as it is as yet, suggests that a functional trait-based approach is promising for the design of agro-ecosystems. We will further elaborate this by putting such approach into the perspective of the management of a landscape, which is characterized by both agricultural crop and livestock diversity and 'wild' (be it planned or unplanned) biodiversity in a certain spatial configuration.

MANAGING SOIL BIODIVERSITY FOR ECOSYSTEM SERVICES: CHALLENGES AND OPPORTUNITIES

Stromberger Mary*^[1], Weir Tiffany^[2]

^[1]Colorado State University ~ Department of Soil and Crop Sciences ~ Fort Collins, Colorado ~ United States ^[2]Colorado State University ~ Horticulture and Landscape Architecture ~ Fort Collins, Colorado ~ United States

Molecular studies have generated significant findings regarding the level of microbial diversity in soil, but we have yet to learn how to effectively capitalize on this diversity to promote beneficial ecosystem services. Soils of high biodiversity are more likely to contain important ecosystem service providers (ESPs), whose presence determines a soil's potential to perform a specific function (e.g., cycle elements, bioremediate contaminants, promote plant growth, etc.) under certain environmental conditions. To benefit from this genetic potential, however, we need a much greater understanding of 1) the important ESPs within a microbial community, 2) the abiotic and biotic factors that influence community diversity and ESP abundance, species composition, and activity, and 3) the spatial and temporal distribution of ESPs and their activities. In this presentation I will discuss the challenges and opportunities of managing soil biodiversity to promote ecosystem services, with an emphasis on crop growth promotion under abiotic stress. I will outline a discover-and-manage approach to promote ecosystem services through assessment of the diversity and abundance of relevant microbial populations, including ACC deaminase positive bacteria, and identification of important abiotic and biotic factors associated with their activity in space and time (through geostatistics and development of predictive models, including decision tree analysis). Once manageable predictors of microbial communities and/or activities are identified, strategies can be developed and implemented to promote their ecosystem services.

The global soil resource is essential to the future survival of humankind and other life on the earth. It is all the more remarkable therefore that we are largely ignorant of what constitutes a healthy soil that is able to sustain the delivery of diverse ecosystem services. We must improve our limited knowledge regarding the biogeography of soil organisms which support such services to develop viable approaches that tackle the global issue of soil degradation. Using data obtained from a unique study of habitats across the UK mainland, we demonstrate, for the first time, that the integration of genotypic, phenotypic and functional measures of soil microbes and invertebrates results in characteristic configurations of soil biodiversity with respect to habitat, irrespective of geographical location. Furthermore, we identified consistent trajectories in these characteristics in a succession from extensive to intensive land use. The results provide clear evidence that multi-taxa approaches that have been globally adopted to define the status of water bodies and terrestrial habitats could be applied to soils to provide a consistent and universal system for characterizing the ecological status of soils. In developing this concept further, we propose that a multivariate approach, which incorporates functional, genotypic and phenotypic traits of soil biodiversity, could be effective in safe-guarding both the organisms and ecosystem processes which underpin soil health and ecosystem services.

TILLAGE-INDUCED CHANGES IN THE FUNCTIONAL DIVERSITY OF SOIL BIOTA

Van Capelle Christine*^[1], Schrader Stefan^[1], Brunotte Joachim^[2]

^[1]Johann Heinrich von Thünen-Institute, Federal Research Institute for Rural Areas, Forestry and Fisheries (vTI) ~ Institute of Biodiversity ~ Braunschweig ~ Germany ^[2]Johann Heinrich von Thünen-Institute, Federal Research Institute for Rural Areas, Forestry and Fisheries (vTI) ~ Institute of Agricultural Technology and Biosystems Engineering ~ Braunschweig ~ Germany

Based on the general strategy to conserve biodiversity and the ecosystem services provided by organisms, there is a need to assess the functional and structural biodiversity in arable soils considering the impact of different tillage systems. Thus, a survey on scientific literature, which has been published during the past six decades, was conducted. We concentrated on data from agroecosystems in Germany as they cover a wide range of different soils, which are representative for temperate regions. The state of knowledge was analyzed covering the impact of conventional, conservation and no-tillage management on lumbricids, collembolans, mites, enchytraeids, nematodes and microbiota. Interaction effects between tillage intensity and parameters characterizing the respective system (e.g. soil texture and crop) were considered. Besides abundance and biomass of soil organisms, species richness and individual densities of taxonomical and functional units, enzyme activities and various quotients indicating microbial-driven soil processes were included in the analysis. The integrating analysis of data sets indicates that soil biota responds specifically to tillage systems. Whereas abundances and species diversity of lumbricids significantly increased, individual density and species diversity of collembolans significantly decreased when tillage intensity was reduced. Tillage-driven impacts on lumbricids and collembolans, thereby, differed depending on soil texture, whereas those on nematodes and microbial communities varied depending on soil depth. Functional groups within certain taxa evince differing tillage-induced impacts. Linking several data sets on various indicator organisms clearly shows that the decision, which tillage system should be applied, must be taken for each individual case, considering local soil characteristics.

A TRIAL WITH ECOSYSTEM SERVICES IN SOIL OF FOUR ARABLE FARMS

Rutgers Michiel^[1], Christian Mulder^[1], Leo Posthuma^[1], Anton J. Schouten^[1], Anton M. Breure^[1], Lijbert Brussaard^[2]

^[1]National Institute for Public Health and the Environment ~ Laboratory for Ecological Risk Assessment ~ Bilthoven ~ Netherlands ^[2]Wageningen University ~ Soil Quality ~ Wageningen ~ Netherlands

A focus on ecosystem services (ES) is key towards a more sustainable management of our natural resources, besides an environmental policy on mitigating the effects of threats like soil pollution and climate change. Many ES rely significantly on the functioning of soils. Consequently, there is an urgent need for rulers and indicators of soil related ES. In the Netherlands, two decades of soil sampling in a monitoring network with the Biological Indicator of Soil Quality (BiSQ) have resulted in a substantial database of soil organisms and their habitat characteristics. Extensive additions from ecological literature have expanded the data set to become a very rich source for both fundamental and practical applications. Abiotic and biotic reference values for soils with a presumed healthy status were derived for ten soil type land use combinations. These references were considered as targets for sustainable land management, for different soil type and land use characteristics. The concept was tested at four arable farms on silt loam in the Netherlands. Overall, ten ES had a lower performance than at the reference sites. However two ES had a higher performance than the reference, i.e. climate functions and natural attenuation. Furthermore, ES were reflected in the typical soil management systems of these four farms, i.e. intensive, conventional (2x) and organic.

Considering the few numbers of bioindicators available to describe and monitor soil quality and to assess soil risk, a national research programme has been set up in France to develop such indicators. The main objectives of this "BioIndicator programme" are to (i) develop methods for measuring soil biodiversity and soil functions (ii) use soil bioindicators to monitor soil quality and (iii) identify relevant bioindicators or endpoints for soil ecological assessment. In this programme involving 70 partners, 47 biological parameters have been tested i.e. microorganisms (e.g. biomass, genetical structure, enzymatic activities), fauna (nematodes, collembola, mites, earthworms, total macrofauna, metal accumulation in snails and in small mammals) and flora (e.g. lipid biomarkers in the leaves, free amino acid content, metal accumulation). These parameters were assessed on 13 sites leading in 47 plots which differ in terms of land use and agricultural practices (e.g. pasture rotation, tillage impact, management), soil type and contamination levels and origins (PAH or metal). The strengths of Bioindicator programme, which is unique at European Union scale, are (i) to test a large number of bioindicators, in a large panel of situations, (ii) to apply standardised sampling protocols managed by only one sampling team, (iii) to manage high number of data (200.000) by using a common database thus facilitates the data analysis, (iv) to collaborate with stakerholders (Ministry, environmental agency, Regional Board for Industry, Research and Environment, farmers, agricultural agency,...). This presentation will present in details the Bioindicator programme (bioindicators, sampling procedures, database, data-mining involved) illustrated by some results.

RESULTS OF A COUNTRY-SCALE SURVEY ON THE EFFECTS OF AGRICULTURAL PRACTICES ON SOIL MESOFAUNA IN HUNGARY

Dombos Miklós^{*[1]}, Gedeon Csongor^[1], Bánszegi Oxana^[1], Szabó József^[1]

^[1]RISSAC HAS ~ Dept. of Environmental Informatics ~ Budapest ~ Hungary

Although certain elements of agricultural practices have been known as main factors of biological soil degradation for decades, data that could show degree of these degradation processes are still limited and insufficient to estimate current ecological status of soils in agricultural landscapes. We will show the results of our country-scale survey (Soil Degradation Subsystem of the National Environmental Information System; details are in Szabó and co-workers' poster) on the effects of agricultural practices on soil biological activity in Hungary. 200 evenly distributed farms from Hungary were randomly selected from the database of the Hungarian Central Statistical Office, according to their agricultural techniques. We recorded all farming activities from tillage to harvest in each farm. Composite soil sampling was carried out in each sampling site in spring 2011. More than one hundred soil physical, chemical and biological properties were measured, which are considered relevant to all soil threats. Regarding the biological properties, abundance, biomass distribution, diversity indices of the mesofauna, and microbial activity were characterized at 200 farms. Traditional soil extraction method and taxonomic analysis for description of the soil microarthropod communities and live extraction followed by image analysis using EDAPHOLOG®/Coll-Scope® systems (see. poster of Gedeon et al.) run parallel for further comparison. In our presentation we will show how the different farming practices - including different agro-environmental schemes, farming practices used in organic and conventional farming systems and the resulting physical and chemical soil degradation (e.g. soil compaction) - influenced the ecological status of arable soils in Hungary.

In the EU, FP7, Project 'EcoFINDERS' (Ecological function and biodiversity indicators in European soils), not only is the normal operating range for the biodiversity of soil organisms across Europe to be determined, but indicators for biodiversity are to be recommended and tested. This will include some of the most recent molecular biological methods (e.g. pyrosequencing, chip technologies) as well as the well tested conventional methods. Indicators for biodiversity were selected at a workshop in Coimbra, Portugal in November 2011 based on a logical sieve approach (Ritz et al 2009). The first section of this presentation will explore in detail the rationale, the process and the results of the indicator selection. The next step is then to deploy the chosen indicators across a range of European soil/land use/habitat scenarios given a project constraint of less than 100 sampling points. The second section of the presentation will describe the GIS/soils database approach to selecting a representative range of sites and outline the sampling regime to be undertaken. (Ritz K et. al., 2009. Ecological Indicators 6:1212)

NEMATODES AS INDICATORS OF SOIL HEALTH AND AGRICULTURAL SUSTAINABILITY: POSSIBILITIES OF THE METHOD WHEN APPLIED AT BOTH A NATIONAL AND EUROPEAN LEVEL.

Stone Dote^{*[1]}, Griffiths Bryan^[1], Creamer Rachel^[1], Sousa José P^[2], Da Conceição I. Luci P. M.^[2]

^[1]Teagasc ~ Crops Environment And Land Use Programme ~ Wexford ~ Ireland ^[2]Universidade de Coimbra ~ Dep. Ciências da Vida ~ Coimbra ~ Portugal

Soil health is an important parameter when estimating the value of a soil resource, especially with regard to agricultural productivity. Soil hosts biodiversity on a range of scales which contribute to the pool of ecological functions and services that can be provided. The FP7 project EcoFINDERS set out to explore and clarify the contribution of soil biodiversity to soil health in light of the many threats to the soil resource pool in our current culture. Soil nematode assemblages have been used as indicators of soil function due to their abundance and diverse contribution within agroecosystems (Yeates, 2003). Within the EcoFINDERS project, it was proposed that an assessment of bio-indicators as tools for determining soil health across European biomes should be carried out. Soil samples from sites across Europe were analysed for nematode abundance. Molecular methods were applied to determine species diversity. Nematode community responses were analysed to assess sensitivity to a range of different disturbances (nutrient additions, tillage, grazing). In addition, as part of the on-going national project to map soils in Ireland, nematode abundance and diversity were assessed. By comparing data ranging from land use to a detailed national scale to the European scale we will present an assessment of the potential of nematodes as indicators of biodiversity, including the practicability of methods (field sampling, extraction and molecular techniques). Yeates, G.W. (2003) Nematodes as soil indicators: functional and biodiversity aspects, *Biology and Fertility of Soils* 37:199–210

METAPROTEOMICS OF LEAF LITTER DECOMPOSITION

Zechmeister-Boltenstern Sophie*^[1], Keiblinger Katharina Maria^[1], Schneider Thomas^[2], Riedel Kathrin^[3]

^[1]BOKU – University of Natural Resources and Life Sciences ~ Department of Forest and Soil Sciences ~ Vienna ~ Austria ^[2]University of Zurich ~ Institute of Plant Biology ~ Zurich ~ Switzerland ^[3]University Greifswald ~ Institute of Microbiology ~ Greifswald ~ Germany

Since almost a decade, metaproteomics is greatly advancing our understanding of microorganisms and their geochemical environment. Most proteins have an intrinsic metabolic function and can thus be used to relate specific microbial activities to defined organisms in multispecies communities. Therefore, the identification of the microbial proteins of a given habitat together with the analysis of their phylogenetic origin and their temporal distribution is expected to provide fundamentally new insights into the role of microbial diversity in biogeochemical processes. We have tested the applicability of the metaproteomic approach in combination with PLFA and enzyme measurements in field and lab studies on beech leaf litter decomposition. Goals of our investigations were: (I) to link structure and function of microbial communities involved in leaf litter decomposition and (II) to investigate the impact of leaf litter stoichiometry and seasonality on the decomposition process. In a mesocosm experiment we also tested the effect of extreme temperatures on litter degradation and the involved microbial community. Our results revealed that resource stoichiometry, i.e. site, had a strong influence on microbial community structure whereas season and temperature extremes most prominently affected community functions. It was possible to at least qualitatively link microbial community structure using metaproteomics to the decomposition process. In addition we were able to link the contribution of major phylogenetic groups to decomposer function. We will also present findings on the application of the method to soil samples and the pros and cons of different protein extraction procedures.

DENITRIFYING BACTERIAL COMMUNITY STRUCTURE AND DENITRIFICATION POTENTIAL AS AFFECTED BY SOIL PROPERTIES IN WETLANDS CREATED IN CHESAPEAKE PIEDMONT, USA

Ahn Changwoo*^[1]

^[1]George Mason University ~ Environmental Science and Policy ~ Fairfax, Virginia ~ United States

Wetland creation is a common practice for compensatory mitigation. Unfortunately, created wetlands often fail to support biotic communities comparable to those in similar, naturally occurring wetlands. Soil parameters in created wetlands are often found not indicative of 'hydric soils' typical of natural wetlands, that support important biogeochemical functions. Denitrification is one of the key biogeochemical functions of natural wetlands and denitrifying bacteria play a significant role in it due to their ability to convert nitrate to gaseous N₂, but little has been known about the role of bacterial community composition in the process. Moreover, there are currently no specific methods and/or designs that would enhance the development of the biogeochemical function in created wetlands. The objective of this study is to investigate the influence of soil properties on denitrification potential (DP), and denitrifying bacterial community structure and diversity in created wetlands. The study was conducted in three mitigation wetlands with varying ages, all created in the Piedmont region of Virginia. A preliminary data analysis has revealed that there were significant differences in gene copy numbers of denitrifying bacterial communities between the wetland sites. T-RFLP fingerprints were related to gene copy numbers obtained by qPCR, and to DEA values overall. Further data analysis is underway. The outcome of the study will provide useful information on how soil properties influence denitrifying bacterial community composition in relation to denitrification function of created wetlands

Soil biogeochemistry domination by Bacteria has driven towards intensive studying of their diversity in such environments. Although the breakthrough of the small ribosomal subunit (SSU) coding gene usage as a molecular marker increased throughput in bacterial diversity studies, it was soon indicated that complex soil environment requirements superseded potentials of past sequence based SSU screening methodologies. Recent high throughput sequencing technologies provided a solution in regards with read numbers but have restrictions concerning analyzed sequence lengths. Aim of the present study was to assess the information potentials according to the multi-million read depths and the SSU single hypervariable (V) region screening limitations provided by novel sequencing technologies for soil environments. V region analysis included database exploration and in silico analysis of literature based generated data. Moreover, samples screened with the referred strategy and were derived from soils that differed in properties due to land use and management, comprised a “real-world” reference for the method application evaluation. Database and in silico analysis indicated that the overall most prominent V region for soil bacterial diversity studies was V3. Soil derived data analysis provided detailed core microbial assemblage (microbiome) comparisons between Illumina screened soils, showing management correlated differences. Resolution abilities also made possible to examine diversity drivers and ecology theory application potentials in the highly complex soil environments used in the present study. Results of this study summarize the reasons according which technologies providing multi-million read sequencing depths are expected to dominate bacterial diversity screening studies during oncoming years.

Whilst the importance of soils and their contribution to ecosystem services provision are well recognised, there is a paucity of knowledge on how particular land-use practices affect different types of soil organisms, and subsequently whether this affects soil functioning. The seventh framework programme EcoFINDERS project (Ecological Function and Biodiversity Indicators in European Soils) aims to “Decipher the links between soil biodiversity, activities, functioning and ecosystem services”. Through this project we have examined soil microbes at a number of European locations ranging from Iberian grassland to boreal forest. At each field site a gradient of land-use intensification has been established permitting investigation of the effects of different land management strategies on microbial communities across a range of climatic zones and soil types. This work focuses on how the diversity and community structure of the different microbial groups are affected at local and regional scales, and the environmental parameters responsible for the perceived differences. We specifically targeted bacteria, archaea and fungi as indicators, and present molecular data showing differential effects in response to anthropogenic and natural environmental gradients. Our results highlight the effect of land-use change on soil microbial communities across Europe and adds to the understanding of how belowground organisms are affected by above ground practices.

S11.02c -3

THE ROLE OF THAUMARCHAEA FOR AMMONIA OXIDATION IN SOIL

Schlöter Michael*^[1]

^[1]Helmholtz Zentrum München ~ Environmental Genomics ~ Oberschleissheim ~ Germany

In the last decade more and more data has been published on the abundance of selected phylogenetic groups of prokaryotes in nature, without having isolates in hand. This holds mainly true for Archaea, which are often very difficult to cultivate using classical approaches. Therefore their physiology and their role for soil health are still not clear and factors driving their activity are still identified more on correlations than on mechanistic based approaches. For example many results have been presented on ammonia oxidizing crenarchaea in different soils under contrasting environmental conditions based on abundance measurements of the amoA gene, however the role of these organisms for nitrification is still unclear and even basic knowledge on autotrophic vs. heterotrophic lifestyle is controversy discussed in literature. In the presentation data based on amplicon sequencing and analysis of metagenomic libraries will be presented to identify drivers for abundance and activity of ammonia oxidizing archaea

S11.02c -4

COMMUNITY COMPOSITION OF AMMONIA OXIDIZING ARCHAEA AND BACTERIA AS A TOOL FOR EVALUATION OF QUALITY OF AGRICULTURAL SOILS

Cuhel Jiri^[1], Maly Stanislav^[1]

^[1]Central Institute for Supervising and Testing in Agriculture ~ Microbiology and Biochemistry ~ Brno ~ Czech Republic

Genetic profiling of ammonia oxidizing bacteria (AOB) and archaea (AOA) using t-RFLP was top-ranked as bioindicator for monitoring of agricultural soils. However, there is a lack of background data of t-RFLP profiles of AO communities among wide range different soils, which is a prerequisite for routine linkage between t-RFLP profiles and soil quality. The aims of the present study were to obtain basic pattern of t-RFLP profiles of AO communities from wide range of agricultural soils at a national scale, and to determine which environmental factors are key drivers of the AO community composition. A set of 77 arable and grassland soils from the Czech Republic was sampled and t-RFLP analysis of the *amoA* gene was conducted. The PCR products were digested with *AluI* and *Bsp143I* restriction enzymes. pH, clay content and urease activity explained 17.4% of the variability of the t-RFLP data of AOA. The relationships among environmental parameters and AO diversity were tighter for AOB, with 42.7% of the variability in the t-RFLP patterns explained by pH, sand content and short-term nitrification activity (SNA). Multiple regression among the soil properties, and individual fragments was calculated. The most significant relationships were found among the AOA-*Bsp143I* – 443 bp fragment and pH, clay content and urease activity ($R^2=0.418$) and among the AOB-*AluI* – 488 bp fragment and pH and SNA ($R^2=0.625$). The Shannon diversity index showed a positive and curvilinear correlation with pH for AOA (*Bsp143I*, $R^2=0.191$) and AOB (*AluI*, $R^2=0.328$), resp.

EROSION OF BIODIVERSITY AFFECTS THE STABILITY OF SOIL MICROBIAL COMMUNITIES

Tardy Vincent^[1], Maron Pierre Alain^[1], Ranjard Lionel^[1], Leveque Jean^[2], Mathieu Olivier^[2], Lemanceau Philippe^[1]

^[1]INRA/Université de Bourgogne ~ Microbiologie du sol et de l'environnement ~ Dijon ~ France ^[2]Université de Bourgogne ~ UMR Biogésociété ~ Dijon ~ France

Anthropogenic activities have led to a significant modification/reduction of biodiversity. By observing this erosion, the understanding of the relationship between biodiversity and ecosystem functioning has emerged as a central issue in ecological and environmental sciences during the last decade. This relationship between diversity-stability-function has been extensively studied by plant ecologists, but remains largely unexplored for soil microorganisms. In this context, we studied the impact of an erosion of biodiversity on the stability of soil microbial communities (i.e. resistance and resilience) in response to two perturbations: a residual metallic stress (mercury input at 20 ppm) and a transient heat stress (50 °C for 24 hours). Microbial diversity erosion was obtained by inoculating sterile soil microcosms with different dilutions of a grassland soil suspension. The response of microbial communities (bacteria and fungi) was evaluated by following the density and the diversity, but also the kinetics of soil carbon mineralization. Our results show that the erosion of diversity affects significantly the resistance and resilience of microbial communities in terms of community dynamics (diversity and density) and functioning whatever the stress. More precisely, the kinetics of soil carbon mineralization is similar between the different levels of diversity, but the intensity of mineralization decreases with the decrease of diversity. When diversity is lower, the heat stress affects more strongly the mineralization than the metallic stress. This study highlights the ecological importance of soil microbial diversity in the ability of a soil to maintain the supply of ecosystem services in fluctuating environmental conditions.

S11.02c -6

EVALUATION OF SOIL QUALITY INDICATORS IN THREE DIFFERENT COLOMBIAN TROPICAL LAND MANAGEMENT AND USES

Gutiérrez Romero Viviana^[1], Martínez Salgado Maria Mercedes^{*[2]}

^[1]Pontificia Universidad Javeriana ~ Microbiología ~ Bogotá ~ Colombia ^[2]Universidad Técnica Federico Santa María ~ Departamento de Industrias ~ Santiago ~ Chile

In Colombia, changes in land use and inappropriate management practices are very common for intensive and extensive crops. Traditionally, physical and chemical parameters are measured to indicate about soil quality regardless a correlation with biological parameters. In the present study, we determined different biological indicators (heterotrophic microbial counts, functional microbial groups and enzyme activity) and its relationship with physical and chemical parameters at three different land uses (forest, pasture and sugar cane crop). Soil samples were taken at 10-cm during a year with 10 sampling events, using a systematic nonaligned design with a GPS receiver. Soil enzyme activities were the most sensitive indicators compared with physical and chemical soil properties, especially β -glucosidase activity that shows a relationship with dehydrogenase activity (77%), pH (70%), clay content (51%), cellulolytic counts (52%) and urease activity (50%). In addition, it was evident a high spatial variability for enzymatic activities related with soil management and use; ecosystems which have been intervened (pasture and sugar cane crop) need a high samples collected to reduce the coefficient of variation. Parameters as phosphorous solubilizing bacteria did not shown any correlation with other indicators evaluated ($p>0.05$), and it is not clear the use of dehydrogenase enzyme as soil quality indicator according to our results.

^[1]IPE-CSIC ~ Biodiversity Conservation and Ecosystem Restoration ~ Jaca ~ Spain ^[2]Université de Rouen ~ Laboratoire d'Ecologie ~ Rouen ~ France ^[3]CIAT ~ Soils Unit ~ Cali ~ Colombia

Soils provide a range of unique ecosystem services such as decomposition, nutrient cycling, carbon sequestration, detoxification and maintenance of soil physico-chemical properties. These services directly or indirectly support many aboveground provisioning and enriching services. A set of proper concepts and ecological theories related to soil biodiversity and its function have been proposed to explain the large variability of soil organisms assembled in complex and diversified communities. Soil organisms act at small scales, whereas their effects may range from local (diseased plants, nutrient mineralization) to very large scales (succession, carbon sequestration, greenhouse gases). For example, most of the macro-aggregate structure of soils is formed by the activities of soil invertebrates and roots, with important consequences for carbon sequestration and water infiltration at several spatial and temporal scales. The diversity of soil organisms may matter more when only few species perform a specific function than for processes that are accounted for by many species. Human activities alter the composition of soil faunal communities, but consequences for ecosystem functioning are poorly understood. Empirical evidence on effects of species diversity on ecosystem processes does not allow generalizations, and requires more studies. The influence of soil spatial variability in shaping species assemblages of soil animal communities is also poorly understood and adds uncertainties to the analysis of ecosystem services derived by soil biological functions. Efforts are required by establishing networks of excellence between researchers among European institutions and to develop a paneuropean program on soil biodiversity and ecosystem service analysis.

CILIATES AS BIOINDICATORS OF SOIL QUALITY: FROM BIOMARKER TO COMMUNITY STRUCTURE ANALYSIS

La Terza Antonietta^{*[1]}, Kumar Santosh^[1], Bharti Daizy^[1], Marinsalti Silvia^[1], Insom Emilio^[1]

^[1]University of Camerino ~ School of Environmental Sciences ~ Camerino ~ Italy

In recent years the potential of protozoan ciliates, as valuable bioindicators of ecosystem quality has been highlighted by a large number of authors. These eukaryotic, single-celled organisms are essential component of freshwater, marine and terrestrial ecosystems. Moreover free-living ciliates, due to their amazing molecular, cellular and physiological flexibility, have been able to colonise every type of environment up to now surveyed, from deep oceans, to polar regions and every soil types. Ciliates shown many desirable characteristics as test organisms for the design of convenient and cost effective assays, from the biomarker to the population-community level, to be used for environmental assessment. Firstly, ciliates occupy the first trophic levels and consequently represent ideal early warning indicators of ecosystem deterioration. Secondly, they play key roles in the transfer of matter and energy within the microbial loop. Moreover, numerous ciliate species can be easily cultured with a short generation time and for some species (i.e. Tetrahymena, Paramecium) genomic data and various molecular tools are available. Thus, this communication aim to describe the potential of ciliates as bioindicators of soil quality and to highlight their usefulness for the development of “prognostic” assays (i.e. able to detect sub-lethal toxicant effects of soil eluates), based on the exploitation of stress gene activation responses (biomarkers and biosensors), as well as, of “diagnostic” assays (i.e. able to detect overall ecosystem impairment), based on the analysis of the community structures of ciliates in arable soils to evaluate the potential impact of different agricultural management.

THE IMPORTANCE OF THE SOIL MICROBIAL COMMUNITY IN REGULATING PATHOGEN DECAY

Moynihan Emma*^[1], Ritz Karl^[2], Tyrrel Sean^[2], Richards Karl^[1], Brennan Fiona^[1]

^[1]Teagasc ~ Crops, Environment and Land Use Research Centre ~ Wexford ~ Ireland ^[2]Cranfield University ~ Department of Environmental Science and Technology ~ Bedfordshire ~ United Kingdom

Land use can greatly influence the soil physicochemical environment. Consequently, different aspects of land use will direct the structure of the microbial community. These include the predominant management strategy, organic and mineral amendments, cropping and tillage practices. An important function of soil is the suppression of microbial pathogens introduced through land-spreading of animal manures. An experiment was conducted to determine the impact of microbial community structure associated with different land uses on pathogen survival. The phenotypic structure of the soil microbial community was determined by phospholipid fatty acid (PLFA) profiling. Soils were also characterized for a range of physico-chemical properties. These soils were inoculated with model pathogenic microorganisms, including Escherichia coli, Salmonella and Listeria species. Pathogen survival was measured over 110 days, and the death rate calculated for each case. Physico-chemical and biotic data, including principal components (PCs) derived from the PLFA profiles, were used in stepwise regression analysis to determine the predominant factor related to pathogen-specific death rates. PC scores were identified as the most significant factor in pathogen decay for all organisms tested ($p < 0.01$), with the exception of an environmentally persistent E. coli isolate. This demonstrates the importance of soil biological quality, specifically the configuration of the microbial community, in pathogen suppression, and provides a possible means to assess the inherent potential of soils to regulate pathogen survival. This may lead to the identification of management strategies which will ultimately accelerate pathogen decay, and therefore improve the safety of agricultural practice.

MYCOTOXIN DEGRADATION BY NEMATODES AND COLLEMBOLANS IN WHEAT STRAW DEPENDING ON SOIL TEXTURE

Wolfarth Friederike^[1], Schrader Stefan^{*[1]}, Oldenburg Elisabeth^[2]

^[1]Johann Heinrich von Thünen-Institute ~ Institute of Biodiversity ~ Braunschweig ~ Germany ^[2]Julius Kühn-Institute ~ Institute for Plant Protection in Field Crops and Grassland ~ Braunschweig ~ Germany

A microcosm-study ($n = 5$) under laboratory conditions was conducted to assess the interaction between soil fauna (*Aphelenchoides saprophilus*, Nematoda and *Folsomia candida*, Collembola) and the mycotoxin deoxynivalenol (DON) produced by *Fusarium* species. Our hypotheses were: (1) soil fauna is able to reduce the DON concentration in wheat straw, (2) the degradation efficiency of soil fauna is affected by different soil texture (sandy loam, silt loam, clay loam). Therefore, microcosms were filled with soil and ground wheat straw (artificially *Fusarium*-infected and DON-contaminated vs. non-infected straw). Soil fauna was introduced in different combinations: collembolans, nematodes, mixed and a control without animals. After 2 and 4 weeks, soil and straw was sampled for analyzing DON concentrations and soil fauna individuals were counted. After 2 weeks DON was reduced throughout all treatments, whereas the highest reduction was determined in the mixed treatment. After 4 weeks the degradation of DON was even higher and again the highest reduction was found in the mixed treatment. In contrast to the abundance pattern of *A. saprophilus*, *F. candida* showed an increase in the non-infected treatments after 2 and 4 weeks. The number of *A. saprophilus* increased mainly in the infected treatment. Differences in DON-concentration and abundances were found to depend on soil texture. We conclude that nematodes and collembolans are able to contribute to the degradation of the mycotoxin DON in wheat straw as an ecosystem service.

QUANTIFYING THE CONTRIBUTION OF FREE-LIVING NEMATODES TO NITROGEN MINERALIZATION IN MINIMALLY DISTURBED SOILS

Gebremikael Mesfin Tsegaye^[1], Buchan David^[1], De Neve Stefaan^[1]

^[1]Gent University ~ Soil Management ~ Gent ~ Belgium

*Free-living nematodes have been estimated to contribute 8-19% to total N mineralization in the soil. Despite abundance, diversity and complex interactions of these nematodes with soil biota, these estimations are based on theoretical food web calculations or on very simplified experiments including only selected few species and often in sterilized media. Data that include the interactions among different groups of nematodes, microbes and plants is rarely available. To address this issue we conducted an incubation experiment for 86 days with and without plants, by extracting and re-inoculating entire nematode populations into soil cores that had been defaunated using low-dose gamma irradiation which selectively kills fauna while minimally disturbing the microbial population. Three treatments were compared on soil either left bare or planted with *Lolium perenne*: control, defaunated and reinoculated (+Nem) and defaunated but not re-inoculated (-Nem). Dynamics in mineral nitrogen, microbial biomass, enzyme activities, phospholipids fatty acids (PLFA), Plant N uptake, nematode population and composition were determined after 7, 30, 45, 65, and 86 days of incubation. Nitrification and total mineral N concentration were found to be significantly higher in +Nem samples comparing to -Nem samples throughout the incubation period in bare microcosms. Significant effects on microbial biomass and enzymatic activities were also recorded. Based on these results it seems that inoculating the entire free-living nematode population increases nitrification and total mineral N concentration in bare microcosms. Data on PLFA, nematode composition and microbes-nematodes-plant interactions effects on N mineralization are currently being measured. The oral presentation includes all these findings.*

ROLE OF CROP RESIDUE MULCHES AND THEIR DECOMPOSITION ON SOIL FUNCTIONS IN CONSERVATION AGRICULTURE

Iqbal Akhtar^[1], Sohaib Aslam^[2], Francois Lafolie^[3], Pierre Benoit^[4], Stephane De Tourdonnet^[5], Patricia Garnier^[4], Eric Scopel^[6], Sylvie Recous^[1]

^[1]INRA ~ UMR FARE ~ Reims ~ France ^[2]INRA ~ UMR EGC ~ Grignon ~ France ^[3]INRA ~ UMR EMMAH ~ Avignon ~ France ^[4]INRA ~ UMR EGC ~ Grignon ~ France ^[5]Montpellier SupAgro ~ UMR Innovation ~ Montpellier ~ France ^[6]CIRAD ~ URP SCRID ~ Atananarivo ~ Madagascar

Core principle of Conservation Agriculture is to maintain soil cover by crop residue mulching or cover crops. Mulching practice affects many agroecosystem services, through water dynamics and C and N transformations (Coppens et al., 2007) and their impact on climate change, water and nutrient cycling and soil biological activity. The objectives of this work were (i) to quantify the effects of biotic (diversity of mulches and soil types) and abiotic (climatic conditions) factors on soil functions such as C stabilization, C and N mineralization and transport, GHG emission, microbial dynamics and diversity; (ii) to assess by modeling how these factors affect agroecosystem services in a range of agricultural conditions met in conservation agriculture of France, Brazil and Madagascar. An experiment was performed in controlled conditions with soil columns. The treatments varied either by the type of residue mulch (*Zea mais* + *Doliquos lablab* or *Triticum aestivum* + *Medicago sativa*), or by the type of soil (sandy or loamy soil) and by the water regime (manipulated through the intensity and frequency of rain applied to the soil columns). The *Pastis_Mulch* model (Findeling et al., 2007) tested on the measured data, was then used to simulate different scenarii, particularly different crop rotations and associations representative of the CA agrosystems (amount and quality of crop mulches), amount and distribution of rainfall (dry and wet years) and types of soil. The results allowed to rank the factors according to their positive and negative effects on the different ecosystem services involved.

In response to soil structural degradation and soil organic matter decline associated with arable crop production, alternative approaches including no tillage or reduced tillage systems have been developed. Farmers, researchers and policy makers in Europe are increasingly interested in exploring the possible benefits of these systems. Many studies worldwide have analysed the impact of tillage systems on soil functioning and crop yields; however, until now no study has aimed to give a comprehensive overview of these systems, including the impacts on soil biodiversity, chemical and physical soil properties, and ecosystem services, while integrating socio-economic sustainability. This information, as well as the selection and monitoring of soil indicators, is crucial to guide practical implementation and policies. The SUSTAIN project, performed in France and the Netherlands, proposes a novel transdisciplinary approach. The main objectives of SUSTAIN are (i) to understand how reduced-tillage systems impact the biodiversity of soil functional groups and soil functions (soil structure maintenance, organic matter and nutrient cycling, water regulation, soil filtering); (ii) to quantify the effects of reduced tillage systems on the ecosystem services (food production, greenhouse-gas mitigation); (iii) to investigate the socio-economic sustainability of reduced-tillage systems; and (iv) to develop and disseminate monitoring tools, such as soil-disturbance indicators and evaluation methods for system sustainability. SUSTAIN assembles a broad spectrum of expertise in soil biology, soil physics, soil chemistry and agronomy as well as tools for integrated soil ecosystem analysis. This expertise is combined with the economic and social evaluation of services provided by soil biodiversity.

~ Soil Biology and Plant Nutrition ~ Göttingen ~ Germany ^[3]Institute for Sugar Beet Research ~ - ~ Göttingen ~ Germany

The effects of different tillage systems on soil nutrients have been studied extensively. However, the linkage between different tillage intensities and microbial community structure and their relationship with ecosystem functions has not been directly investigated. In this study, we therefore investigated the long-term effects of mouldboard plough (30cm), cultivator (15cm) and no tillage on microbial activity (basal respiration), biomass (C, N and S) and microbial residues. A strong increase in the stocks of soil organic carbon, total N, P and S were found in the order cultivator > no tillage >> mouldboard plough in the soil profile (0-40cm). The mean stocks of microbial biomass C was 13 and 5% higher under cultivator treatment in comparison with mouldboard plough and no tillage, respectively. The cultivator treatment increased the mean stocks of microbial biomass N and fungal ergosterol significantly (31 and 21%, respectively) compared with no-tillage and mouldboard plough, but had no effect on the stocks of microbial biomass S. The microbial biomass C/soil organic carbon ratio was significantly higher (2.1) in the cultivator treatment and exhibited inverse relationship with the metabolic quotient. The highest ergosterol/microbial biomass C ratio (0.38%) and fungal C/bacterial C ratio (2.2) under the cultivator treatment indicate the abundance of saprotrophic fungi compared with mouldboard plough and no tillage. In summary, our results showed that the higher proportion of fungal biomass and residual C under cultivator system can provide stability in soil nutrients by increasing the role of saprotrophic fungi in soil organic matter dynamics.

Functioning as ecotons, floodplains usually provide shelter for many organisms. However, these ecosystems have been largely submitted to human pressure through the embanking of rivers. Such damages have led to river restoration projects in order to re-establish a near-natural alluvial dynamics and to recover floodplains biodiversity and naturalness. Focusing on soils, we aimed at using biological and pedological descriptors to assess the success of river restoration: i) earthworm communities, ii) humus forms and iii) soil structure and porosity. Two floodplains were compared: i) on one hand, the Emme River which presents an embanked (EE) and a restored site (ER), ii) on the other hand, the Rhine River, never embanked, which represents the near-natural reference (NR). Our main assumption was that earthworm communities, humus forms and soil parameters increase in terms of diversity, typicity and evolution along a gradient of naturalness from the embanked system to the near-natural reference. First results show that earthworm's communities tend to be quite similar in terms of abundance, species and ecological categories for ER and NR sites. Humus forms, most of them being psammofoms, seem to be better developed in the NR site compared to EE and ER sites. Soils structure and porosity appear to be greater developed after river restoration (ER) and tend to approach values of the near-natural reference. Further statistical analyses are however needed and will be performed to better highlight the effect of river restoration.

BIOGENIC SOIL STRUCTURES: FEEDBACKS BETWEEN BIOACTIVITY AND SOIL HYDROLOGY

Van Schaik Loes*^[1], Schröder Boris^[1], Zehe Erwin^[2], Eccard Jana^[3]

^[1]University of Potsdam ~ Institute of Earth and Environmental Science ~ Potsdam ~ Germany ^[2]Karlsruhe Institute of Technology ~ Institute of Water Resources and River Basin Management ~ Karlsruhe ~ Germany ^[3]University of Potsdam ~ Institut für Biochemie und Biologie ~ Potsdam ~ Germany

Bioactivity influences the hydrological processes through creation of biogenic soil structures, thereby changing infiltration and drainage patterns. At the same time, however, the species distribution also depends on soil moisture contents. Therefore including the feedbacks between bioactivity and soil hydrology is crucial for getting reliable predictions of catchment scale hydrological behavior under land use change and climate change. Different organisms are known to strongly influence soil structure through the creation of macroaggregates and macropores: most commonly earthworms, rodents, moles, and roots but also shrinkage in clay soils is an important abiotic origin of macropores. The spatial distribution of these soil organisms leads to both a variability in local soil structure and thus local infiltration patterns as well as varying degrees of connectivity of local macropore patterns at larger scales. Thus, local information on bioactivity - as the origin of macroporosity - may be used as an indicator for spatial variability of water storage and fluxes at the small scale, whereas knowledge on the spatial distribution and connectivity of the small scale macroporous networks is necessary to understand the influence of soil structure on the hydrology at larger scales. As a part of the CAOS (Catchments as Organised Systems) Project we will therefore link spatial distributions of main soil organisms to resulting spatial patterns of macropores, with the final aim to improve hydrological modeling of water storage and fluxes in the topsoil at different scales.

^[1]Chinese Academy of Sciences ~ Institute of Soil Science ~ Nanjing ~ China ^[2]Nanjing University, ~ State Key Laboratory of Pollution Control and Resource Reuse, School of the Environment ~ Nanjing ~ China ^[3]State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ Christmas Island ^[4]State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China ^[5]State Key Laboratory of Pollution Control and Resource Reuse, School of the Environment ~ Nanjing University ~ Xianlin Avenue 163, Nanjing ~ China

Soil organic matter (SOM) plays crucial role in relation to global carbon cycling, sustainable agricultural systems and the sequestration of micropollutants in soils. Earthworms are commonly the predominant soil fauna in most terrestrial ecosystem, and have significant effects on the SOM stability, soil microbial community and activity. However, the transformation of SOM by earthworms and the involved mechanisms are still obscure. In the present study, we prepared ¹⁴C-labeled SOM [either homogenously labeled or specifically labeled by ¹⁴C (in the aromatic or the proteinaceous component of humic substances)], ¹⁴C-labeled microbial biomass [fungi (*Penicillium chrysogenum*), bacteria (*Escherichia coli* and *Bacillus megaterium*)] and ¹⁴C-labeled cell components (protein, peptidoglycan and chitin), and investigate the degradation and transformation of these substrates in soil with the presence of the geophagous earthworm *Metaphire guillelmi*. Our results indicated that *M. guillelmi* can utilize the recalcitrant SOM (humic substances, HS) as their energy and nutrient sources owing to the selectively digestion of the proteinaceous components of HS. The results also showed that *M. guillelmi* not only significantly stimulated the mineralization of microbial biomass and its cell components, but also utilized them as nutrient and energy sources. Findings of this study provide the first direct evidences that earthworms could selectively digest the proteinaceous components of HS and utilize microbial biomass and its cell components as food sources, which underline the crucial role of the earthworms play on the decomposition and stabilization of SOM in soils.

*Bacterial wilt (BW), caused by *Ralstonia solanacearum*, is a major constraint in production of tomatoes and many other crops in tropical, subtropical regions, as well as in warm temperate regions. Because the efficacy of conventional methods to control BW is limited, there is an urgent need to develop and evaluate biologically based and environmentally safe, alternative control methods. Therefore, the objectives were to: 1) determine the potential of plants possessing biocontrol properties to control BW of tomato and affect non-targeted soil microbial community and activities; and 2) identify microbial properties as indicators of disease suppressive soils. The relative BW suppressiveness was determined for six plant species grown at two densities (*Mucuna deeringiana*, *Crotalaria spectabilis*, *Crotalaria juncea*, *Allium fistulosum*, *Raphanus sativus*, *Tagetes patula*) that were harvested, incorporated into soil and allowed to decompose for ten days. At the end of the plant growth stage, for *A. fistulosum*, *C. juncea* or *C. spectabilis*, tomato BW was dramatically reduced. BW incidence also correlated negatively with Gram-, Gram+ and Actinomycetes indicating an antagonistic effect of the microbial community against *R. solanacearum*. BW negatively correlated with soil NO₃- and plant biomass indicating that high plant biomass incorporation and high NO₃- availability may impede *R. solanacearum* pathogenicity. *A. fistulosum*, *C. juncea* and *C. spectabilis* have potential as BW biocontrol agents in rotation with tomato where this effect could be due to direct alleochemical effects of the roots (e.g. root exudates) and/or stimulation of a microbial component that suppresses tomato BW disease.*

*Soil fauna are commonly understood to accelerate the process of litter decomposition. It is yet unknown how different groups of soil fauna alter the decomposition process in ways that may change the relative amount of carbon (C) mineralized and lost as CO₂ vs. that stored in the soil as soil organic matter (SOM). Soil fauna may increase litter fragmentation or regulate the soil microbial community involved in decomposition, thus altering the physical and biological pathways underlying decomposition and affecting our ability to accurately model C cycling. In order to examine the importance of this soil biodiversity on decomposition, we incubated ¹³C and ¹⁵N enriched leaf litter (*Andropogon gerardii*) in a native tallgrass prairie in Kansas, USA. We applied a naphthalene treatment to manipulate soil fauna. Over the first year of decomposition, we traced the decomposing litter C, both with soil fauna and with naphthalene repellent, into CO₂ fluxes, SOM fractions, dissolved organic carbon, the microbial community using phospholipid fatty acid biomarkers (PLFA), and soil fauna (nematodes and microarthropods). Initial results indicate that although decreased soil fauna decreases the rate of litter mass loss, it may not significantly alter the relative mineralization of litter C to CO₂ vs. that stored in the soil. We find that the presence of soil fauna reduced microbial biomass, in particular the abundance of fungi and gram-negative bacteria, but soil fauna clearly increased microbial litter-C utilization.*

Soil microorganisms play a pivotal role in soil organic matter (SOM) turn-over and their diversity is discussed as a key to the function of soil ecosystems. However, the extent to which SOM dynamics may be linked to changes in soil microbial diversity remains largely unknown. In our study we characterized organic matter degradation along a microbial diversity gradient in microcosms amended with ¹³C labeled wheat residues in order to assess whether organic matter decomposition is linked to soil microbial diversity. During incubation, respiration as well as the priming-effect was strongly linked to microbial diversity, with the highest values observed where diversity was greatest. After 60 days, nuclear magnetic resonance (NMR) analyses showed similar spectra for original wheat material and soil from the lowest diversity treatment indicating little degradation at low microbial diversity. A positive correlation between the alkyl/O-alkyl ratio and initial Shannon's index could be established. Soil lignin content was similar irrespective of microbial diversity. However, ¹³C compound specific analyses showed that vanillyl-lignin units were less degraded if microbial diversity was low. In contrast, soil sugar content as well as relative contents of the wheat specific sugars arabinose and xylose increased with decreasing diversity indicating that more sugars were used if microbial diversity was high. We conclude that microbial diversity alters the decomposition of the different plant litter biopolymers. Independent of their redundancy, functions of organic carbon decomposition are affected by microbial diversity.

Decomposition of organic matter in forest soils is a complex process where both fungi and bacteria participate. The aim of this study was to explore the diversity of bacteria and fungi active in decomposition with a special emphasis on cellulose and hemicellulose hydrolysis. To achieve this, characterization of microbial community and selected decomposition-related genes was performed by pyrosequencing of soil DNA and RNA and combined with stable isotope probing and the extracellular proteome was analysed by mass spectrometry and enzyme activity (EEA). In Picea abies forest soil, summer represents a period with high input of photosynthate C via plant roots, while in winter the decomposition processes dominate. Bacterial communities (>10 000 OTUs) were dominated by Acidobacteria, Proteobacteria and Actinomycetes, while fungi (>1000 OTUs) mainly belonged to Ascomycetes and Basidiomycetes reflected the seasonal differences in decomposition. The seasons were also characterised by the differences in abundance of functional genes in the soil metagenome including the decomposition-related genes. Genes encoding for cellulase, glucuronidase and oxalate decarboxylase showed distinct association with different soil horizons indicating the presence of different fungal communities at different soil depths. The analysis of genes involved in hemicellulose and pectin decomposition also showed that the communities of their producers are highly diverse. The metaproteome analysis revealed the dominance of fungi over bacteria in the production of hydrolytic enzymes in soil.

Boreal forests act as a global sink of carbon due to a large accumulation of recalcitrant organic matter. Nitrogen is immobilized in organic compounds, leading to low plant nutrient availability in these ecosystems. Fungal peroxidases (ClassII) are likely to play a key role in degrading recalcitrant polyphenolic compounds of leaf litter and humus in boreal forest soils. These enzymes have mainly been studied in model "white rot" wood decomposers, but peroxidase activity is also commonly measured in humus. In soil, typical "white-rotters" are absent but, instead, ectomycorrhizal fungi predominate. It has often been reported that peroxidase activity increases under low nitrogen availability, suggesting a key role of these enzymes for fungal nitrogen mobilization. When fungi forage for nitrogen, carbon could be released as a side effect. Previously, we found that peroxidase-encoding genes are widely spread among ectomycorrhizal genomes. In particular, a group of Cortinarius species contained several peroxidase genes each. In order to investigate whether mycorrhizal peroxidase genes are actively expressed and if their regulation responds to nitrogen, we performed field trials in a subarctic birch forest and a boreal pine forest. Enzyme assays showed that Mn-peroxidase activity was twice as high on control plots compared to fertilized ones. Furthermore, we detected co-localization of high peroxidase activity and several different ectomycorrhizal Cortinarius species and could even show expression of manganese peroxidase genes by Cortinarius in forest soils. Thus, we hypothesize, that this particular genus is an ecologically important key player in decomposition of recalcitrant carbon in boreal forest ecosystems.

Numerous studies have highlighted the impact of litter quality on soil inhabiting biota. It is now admitted that resources derived from roots are intimately linked to soil biota assemblages. Our study focuses on changes in both collembolan and microbial assemblages and their relationships with the biochemical composition of their trophic resources (e.g. litter and roots). Sampling was done in five plant assemblages: short grassland, tall grassland, encroached grassland, shrubland and forest. Litter and root biochemical composition were assessed by stepwise chemical digestion, allowing a quantification of four quality fractions: cell solubles, hemicellulose, cellulose and lignin. Both cell solubles and lignin contribution increased significantly during the succession. Mean abundance and rarefied richness of Collembola significantly increased from herbaceous stages to woody stages. This pattern was also observed for bacterial biomass and both hemiedaphic and euedaphic species abundance. Biochemical fractions derived from litter and root significantly explained variances of Collembola and microbial assemblage. Epedaphic species did not show any significant relationship with litter or root biochemical composition. Conversely, hemiedaphic and euedaphic group community pattern could be explained by fungal and bacterial abundances, respectively and by litter and root biochemical fractions. Our results clearly indicate that the quality of plant resources entering the soil food web could be a good predictor of soil Collembola and microbial assemblages. Further, segregation of Collembola in functional group appeared to be an interesting alternative for aboveground belowground studies. Our study provides an interesting conceptual framework to explore the relationships between above and belowground subsystems.

MODELING LITTER DECOMPOSITION: MICROBIAL AND LITTER BIOCHEMISTRY CONTROLS

Lashermes Gwenaëlle^{*[1]}, Daryl L. Moorhead^[2], Isabelle Bertrand^[1], Sylvie Recous^[1]

^[1]INRA ~ UMR614 Fractionnement des Agro-Ressources et Environnement ~ Reims ~ France ^[2]University of Toledo ~ Department of Environmental Sciences ~ Toledo ~ United States

The decomposition of plant litter is a complex ecological process and different levels of this complexity have been represented in mathematical models. Moorhead and Sinsabaugh (2006) developed the GDM (Guild Decomposition Model) that describes the decomposer community as three functional guilds, each guild associated with the decomposition of a major pool of litter constituent: soluble compounds, holocellulose or lignin. It also describes the interactions between holocellulose and lignin, manifest as mutual feedback controls on microbial activities. For the first time, GDM was tested against data using detailed observations simultaneously describing C mineralization and changes in litter biochemistry during maize root decay (Machinet et al. 2009). The theoretical parameters were tested and discrepancies between observations and simulations were analyzed to improve the model as follow: i) initial microbial activity was increased, ii) the structure of GDM was changed to route all degradation products into the soluble pool available for microbial assimilation, and iii) the control of holocellulose degradation by lignin was modified. The revised model was then successfully tested with results of an independent experiment using 16 maize root genotypes (Machinet et al. 2011). Our results showed that litter decay shifts from early limitation by microbial activity to later limitation by substrate quality. It also revealed strong controls of litter quality on initial rates of microbial activity. Differences between observations and simulations over the long-term were best explained by phenol acid contents, which contribute to structural cell-wall networks, demonstrating the importance of representing interactions between biochemical constituents in decomposition models.

Veterinary antibiotics enter the environment via manure application and influence soil organisms and nutrient cycles. The present study gives information on the impact of antibiotics amended to soil with manure from pigs treated with sulfadiazine (SDZ) and difloxacin (DIF), respectively, on nitrogen turnover and on the functional diversity of microorganisms in bulk soil and rhizosphere. Therefore, the actual and potential nitrogen mineralization, denitrification and nitrification activity as well as the abundance of the corresponding functional microbial groups were tracked over 62 days in a mesocosm experiment under controlled moisture, temperature and light conditions. The mesocosms contained an agricultural soil (Orthic Luvisol) mixed with manure from untreated, SDZ- and DIF-treated pigs at amounts of agricultural relevance. Pre-grown maize seedlings were cultivated on the soil. Microbial analyses were performed at the beginning and in distinct intervals up to 62 days after manure addition. The microbial biomass and nitrogen turnover processes were stimulated by manure application. The presence of SDZ restricted the enhancing effect of manure. The potential nitrification showed comparable and significantly decreased activities in both soil compartments till the end of incubation while the impact on the potential denitrification was more pronounced in rhizosphere. The gene abundance was not changed. In contrast, DIF applications caused minor effects on gene abundance and no effects on activity. This can be attributed to fast adsorption of DIF. The observed effects on the soil microbial functions particularly in the rhizosphere represent a potential risk of antibiotics already effective in medically caused concentrations in manure.

It is becoming increasingly important to reduce nitrogen (N) losses from agricultural soils. Nitrogen, in the form of nitrate (NO₃-), is highly soluble and is easily leached from soil, potentially resulting in contaminated receiving waters. NO₃- can also be sequentially reduced by microbial denitrifiers to the gaseous end products NO, N₂O and N₂. Reduction of N₂O emission from soils is of particular interest, as it is an important greenhouse gas. One solution currently being explored for the reduction of N-losses is the use of nitrification inhibitors, which temporarily inhibit ammonium oxidation. Dicyandiamide (DCD) is widely used in some countries but despite its common use, its impact on the N cycling microbial community remains unclear. We investigated the impact of DCD on the microbial community in slurry amended grassland soil. Microcosm incubations of three contrasting temperate grassland soils were conducted over a 20 day period at 15°C. Microcosms were amended with slurry with or without DCD and 15N isotopic labelling was applied to the samples, to allow the determination of several simultaneously occurring gross N transformation rates. Abundance of ammonium oxidizers and denitrifiers were quantified by targeting functional genes using qPCR. Soil mineral N (NH₄⁺, NO₃⁻) concentrations, gaseous losses (N₂, N₂O) and the 15N enrichment of these N compounds, were analysed over the time period. Post incubation, higher ammonium concentrations (0.125 instead of 0.008 NH₄⁺ mg N/g) and lower nitrate concentrations (0.125 instead of 0.256 NO₃mg N/g) were found in the DCD soils indicating nitrification inhibition, which subsequently affected N-losses.

The relevance of climate change on nitrogen turnover processes in soils is still not completely understood. Nitrification and denitrification are important drivers of N₂O emission from soils. The influence of elevated atmospheric CO₂ concentration, elevated temperature, changed precipitation patterns and drought on N₂O emissions as well as the abundance and activity of ammonia oxidizing and denitrifying microorganisms were investigated in five different field experiments in agricultural ecosystems. Elevated atmospheric CO₂ increased the growth and nutrient uptake of crop plants leading to decreased N₂O production rates in an arable soil, whereas ammonia oxidizer and denitrifier abundances were more affected by seasonal variations in soil moisture than by elevated CO₂. In a grassland ecosystem elevated CO₂ was found to increase N₂O emissions, but the CO₂ effect was restricted to sites with increased soil moisture. Elevated soil temperature doubled N₂O emissions of an arable field although soil water content in the top soil layer was reduced in comparison to ambient temperature. Drought periods decreased the abundance of denitrifying bacteria in soil, but showed only minor effects on potential denitrification rates. Data of the different experiments will be presented to enlighten possible changes and feedbacks of the N-cycle in soils under future climate change scenarios.

TEMPORAL EVOLUTION OF GROSS N MINERALIZATION AND NITRIFICATION RATES IN INTACT SOIL CORES IN A POPLAR PLANTATION FROM SOUTHERN GERMANY.

Díaz-Pinés Eugenio^[1], Dannenmann Michael^[1], Butterbach-Bahl Klaus^[1]

^[1]Karlsruhe Institute of Technology ~ Institute for Meteorology and Climate Research. Atmospheric and Environmental Research ~ Garmisch-Partenkirchen ~ Germany

Deeper understanding of N transformation processes in the soil, including temporal dynamics is needed. To this purpose, analysis on undisturbed soil samples is a strongly desired. Here, we present results of gross N mineralization and nitrification rates in a poplar plantation (Swabian Alps, southern Germany) over one growing period. We applied the 15N pool dilution technique, in which the 15N labeled solution is homogenously applied by micro syringes in the intact soil core. This allows the estimation of the rates without disturbing the original structure of the soil. Our preliminary results show a strong dependence of N turnover processes on temperature and soil moisture status, and a predominant role of N mineralization in comparison to nitrification. Additionally, we relate the N turnover rates with results of microbial C and N, NH₄⁺ and NO₃⁻ contents in the soil solution as well as trace gas emissions (CO₂, CH₄ and N₂O) from field campaigns with automatic measurement systems. These results will contribute to the understanding the N turnover processes in the soil, and allow the improvement and further development of models to better predict future N₂O and other GHG emissions in a changing environment.

The most common parameter related to nitrogen (N) leaching from forest ecosystems has been the C/N quota of the humus layer, plant N uptake and enhanced N mineralization, but the role of ectomycorrhizal fungi (EMF) has been less clear. Almost all boreal and temperate forest tree species live in symbiosis with EMF, the trees transfer carbon to the fungi in exchange for nutrients and water. When inorganic N is added to N deficient soils the symbiosis becomes repressed and EMF growth reduced since the fungal symbiont is less needed for the tree. This might lead to enhanced N leaching as the efficient nutrient uptake by the fine EMF mycelial network is reduced, and it has been observed that high N leaching coincided with reduced EMF mycelial growth in an oak forest N deposition experiment. To separate the effect of EMF growth from other environmental variables the project was set up, in the Swedish throughfall monitoring network, at 30 Norway spruce forest locations monitored for deposition, soil water chemistry, needle chemistry and vegetation. We analysed growth of EMF extraradical mycelium by using sand filled mesh-bags, a pore size of 50 μm allowed for penetration of EMF mycelium but prevented ingrowth of the coarser plant roots. I will present how growth of EMF correlated with the monitored environmental parameters, such as N deposition (spanning a gradient of 2 - 20 kg ha⁻¹ ya⁻¹), and if it affected the leaching of N (spanning a gradient of <0.01 - 4.83 mg l⁻¹).

Wetlands cover about 6% of the world landscape. Within such lands, the dominant classes, bogs and fens, are highly important for the C cycle and in particular peatlands, sequestering about one-third of the terrestrial C, are critical ecosystems, which need to be largely investigated for their microbial diversity and roles. So far, more than 50% of the areas of peatlands, wetlands and riparian zones have been lost, through conversion to agricultural use. Intensive agriculture involving the drainage of peatlands has been shown to lead to major problems because of the oxidation, subsidence and severe CO₂ emissions. Several studies have been performed on secondary plant community succession and soil chemical changes after field abandonment in various habitats, whereas little is known about the accompanying belowground microbial diversity and the factors driving such shifts. In this regard, some studies have evaluated the effects of land use changes, such as forest, grassland and meadow restoration, or land abandonment on the microbial secondary composition and structure, but there is a lack of information regarding peatlands. To address this gap of knowledge, here, we investigated the community composition and structure of nitrifying and denitrifying bacteria, oxidising archaea and arbuscular mycorrhizal fungi in a peatland secondary succession, after being abandoned for 6 years, around the Massaciuccoli Lake (Tuscany, Italy). Arable cropping systems were used as controls. Diversity was determined by DNA cloning and sequencing. Phylogenetical analyses and multivariate methods using soil chemical parameters as environmental factors allowed us to highlight clear patterns of microbial secondary succession.

To understand the impacts of precipitation patterns and changes in these patterns on the microbial communities and the processes they catalyze in semi-arid soils, we investigated the consequences of dry-down periods of different lengths and we followed community response to the first rainfall following a long dry period using two California annual grassland soils. Longer periods of dry-down before rainfall significantly increased the soil CO₂ efflux. DNA and RNA was extracted from soil was used to characterize the physiological status of communities during dry down and wet up. A long preceding dry period results in destruction of more bacterial and fungal cells, which may be fuelling the larger pulses of CO₂. We identified three response strategies to wet up events based on when taxa had the highest relative ribosomal quantity: rapid-responders (within 1 hour of wet-up), intermediate-responders (between 3 and 24 hours following wet-up), and delayed-responders (24 to 72 hours post wet-up). These data suggest that the large carbon dioxide pulse produced concurrently with wet-up results from the activity of different groups of metabolically active microorganisms over time. Relative ribosomal quantity of rapid-responders was as high in the prewet dry soils as at any other time, suggesting that some organisms may be poised to respond to the wet-up event in that they preserve their capacity to synthesize proteins rapidly. Microbial response patterns clustered phylogenetically, and were primarily conserved at the phylum level, with the clustering of responses largely consistent across the two soils.

Microbial communities exist and are active in a complex 3-D physical framework which causes a variety of microenvironments to develop that are more or less suitable for microbial growth and activity. If there is a significant microbial biogeography at the pore scale in soil, then the relationship between microbial diversity and ecosystem function is likely to be affected by micro-environmental variations at the pore scale. Here, we show that there is a significant pore-scale microbial biogeography by labelling microbial communities in different pore size classes of undisturbed soil cores with ¹³C-labelled fructose. This was achieved by adding the substrate solution to the samples at different matric potentials (-100 kPa, -3.15 kPa and -1 kPa; placing the substrate in pores with maximum diameter of 0.97, 9.7 and 97 mm, respectively) and incubating the samples for two weeks. The structure of microbial communities in different pore size classes was measured by PLFA stable-isotope probing. Labelled PLFA profiles showed that microbial community structure differed significantly among pore size classes. In order to determine the origin of the biogeography (due to historical or contemporary environmental conditions), we cross-inoculated two sterilised soils at different matric potentials and incubated them for 10 months. The contribution of historical (differences related to inoculum) and contemporary events (differences related to soil and pore properties) to community structure was determined by ARISA. The results suggest that each contributed significantly to differentiation among communities.

S11.06 -3

'MICROBIAL LOGISTICS' - MYCELIA AS NETWORKS FOR FUNCTIONAL DISPERSAL OF BACTERIA AND CHEMICALS IN SOIL

Wick Lukas Yvo^{*[1]}, Furuno Shoko^[1], Foß Susan^[1], Banitz Thomas^[1], Harms Hauke^[1]

^[1]Helmholtz Centre for Environmental Research UFZ ~ Environmental Microbiology ~ Leipzig ~ Germany

The term 'logistics' (i.e. having the right thing, at the right place, at the right time) applies for the biodegradation of contaminants in soil. Degrading bacterial communities walk the tightrope of contaminant availability and suitable physical habitats for their activity; this situation is often aggravated by the concurrence of restricted bacterial mobility and retarded transfer of hydrophobic organic contaminants (HOC) in soil. In order to cope with heterogeneous environments mycelial fungi therefore have developed a unique network-based growth form. Unlike bacteria mycelia spread ubiquitously in the soil, penetrate air-water interfaces and cross over air-filled pores between the bacteria and contaminants in the vadose. In air-filled soil, enhanced homogenization of bacteria and contaminants can be achieved by bridging physical air gaps with fungal hyphae thus enabling substrate-directed mobilization of bacteria along chemical gradients. In this contribution we demonstrate the biodegradation-enhancing influence of mycelial dispersal networks on both the microbial transport and the translocation of HOC. Our data show that mycelial networks (i) act as effective dispersal networks for both undirected and targeted (chemotactic) mobilization of contaminant degrading bacteria ('fungal highways'), (ii) increase the mobility of a wide range of HOC due to their translocation in their cytoplasmic streaming ('fungal pipelines'), and thus (iii) improve the accessibility of bacteria to soil contaminants and, concomitantly, their biodegradation. Given their ubiquity and length of up to 1000 m g⁻¹ dry soil mycelial networks hence appear to play a significant role in the microbial biogeography for the ecosystem service of contaminant biodegradation in soil.

Even though rhizospheric pH displays high variability, possible links between pH and bacterial biogeography at the rhizosphere scale remain largely unknown. The aim of this study was to document the spatial distribution of bacterial communities in relation to soil pH around roots of two functionally contrasting plants, a coniferous tree and an annual legume. *Pinus pinaster*, with and without ectomycorrhizal inoculation (*Rhizopogon roseolus*), and two *Medicago truncatula* genotypes (Jemalong 6 and DZA 315-16), inoculated with *Sinorhizobium medicae*, were cultivated in thin mini-rhizoboxes. After two months, millimetre-scale mapping of the following parameters were performed on 18 cm² zones: presence of roots, mycorrhizae and nodules; soil pH, using non-invasive planar optodes; and different taxonomic and functional (nitrifiers and denitrifiers) groups of bacteria, using Q-PCR. Rhizosphere acidity was highly heterogeneous, with lowest pH close to mycorrhizal roots of *Pinus pinaster* and nodules and dense roots of *Medicago truncatula*. Both soil pH and quantities of bacterial phyla showed highest variability in the rhizosphere of *Pinus pinaster* with mycorrhiza, followed, in order of decreasing variability, by *Medicago truncatula* DZA 315-16, *Medicago truncatula* Jemalong J6, and *Pinus pinaster* without mycorrhiza. The spatial patterns of bacterial phyla were consistently related to soil pH, with the strongest relationship in the rhizosphere of *Pinus pinaster* with mycorrhizal inoculation. This pioneering documentation of bacterial biogeography at the rhizosphere scale provides completely new insights in how mycorrhizal and nitrogen-fixing symbioses generate spatial heterogeneity in soil pH and bacterial community composition.

S11.06 -5

UNDERSTANDING SOIL MICROBIAL COMMUNITY SPATIAL PATTERNS AT MULTIPLE SCALES BY FOCUSING ON HABITAT PATCHES IN THE LANDSCAPE

Blackwood Christopher*^[1]

^[1]Kent State University ~ Department of Biological Sciences ~ Kent ~ United States

*It is well known that biogeographic patterns depend on the spatial scales investigated, although the mechanism behind this pattern, and the implications for ecosystem functions, are not necessarily clear. We have found that the effect of spatial scale on biogeographic patterns in microbial communities may arise from the different ways in which habitat patches and edges are treated at different scales. For example, we found that soil microbial communities in a well-defined habitat, the rhizosphere of *Lobelia siphilitica*, were spatially autocorrelated but independent of soil conditions on a regional scale, a pattern consistent with dispersal limitation and neutral dynamics. In contrast, microbial communities at the same sites but associated with random plant species were correlated with soil properties but were not spatially autocorrelated, and were therefore consistent with species sorting according to their ecological niches. To understand mechanisms behind contrasting patterns such as this, we have begun investigating the biogeography of microorganisms in well-defined habitat patches. In individual leaves and leaf neighborhoods in the Oi horizon, fungal community composition appears to be consistent with dispersal limitation. Scaling up from leaf neighborhoods, we found evidence for species sorting among forest types. However, the consistency of species sorting in the microbial community is dramatically reduced at forest patch edges, indicating that dispersal limitation still plays an important role. Finally, extracellular enzyme activities appear to be largely independent of variation in microbial community composition, indicating the important role of functional redundancy in microbial systems.*

^[3]Université de Lyon ~ Laboratoire de Biométrie et Biologie Evolutive ~ Lyon ~ France

Soil houses a huge biodiversity involved in ecological services through microbial community assembly. However, processes driving soil microbial community assembly are still scarcely understood, particularly the relative importance of environmental heterogeneity regarding to dispersal limitations. This can be achieved through studying the determinism of taxa-area relationship (TAR, how community composition change with geographic distance), a fundamental relationship in ecology. Here, a biogeographical approach was applied on a wide scale to evaluate TAR for soil bacterial and fungal communities and to partition their spatial variations into environmental heterogeneity effects and dispersal limitations effects. Four contrasted regions, extracted from the French soil quality monitoring network, were considered: Brittany, Burgundy, Landes and South-East. The genetic structure of indigenous bacterial and fungal communities was determined by molecular fingerprinting and their TARs were evaluated. Significant TARs were observed in Brittany and South-East for both bacteria and fungi, and only for bacteria in Burgundy. The turnover rates of bacterial and fungal communities were in the same order of magnitude between regions and microbial groups despite different environmental patterns among regions. Distance-based canonical redundancy analysis was used to confront genetic data to soil physico-chemical characteristics, climatic conditions, land use and site location (a descriptor for dispersal limitations). Spatial variations of soil bacterial and fungal communities' assembly were mainly explained by environmental heterogeneity (15% to 36% of variance). Dispersal limitations explained smaller but significant amounts of variance in only two regions (ca. 3%). Among environmental factors, pH ranked first but their hierarchy changed with region and organism type.

S11.06 -7

SOIL BACTERIAL BIOGEOGRAPHY - WHERE DOES THE MAP LEAD US?

Griffiths Rob^[1], Thomson Bruce^{*[1]}

^[1]CEH ~ Microbial Ecology ~ Wallingford ~ United Kingdom

A decade ago, the notion that we could draw up predictive maps of soil bacterial biodiversity across landscapes may have seemed an ambitious and possibly unattainable objective. However, over the past 5 years a number of molecular studies have emerged documenting the predictable response of bacterial biodiversity to soil edaphic gradients, meaning that such ambitions are now a reality. Here I discuss these studies in relation to our own work in mapping the soil biodiversity across Great Britain. What do these studies mean for our overall understanding of the driving forces shaping soil bacterial communities? Is “everything everywhere” meaning we shouldn’t concern ourselves with biodiversity, or are the methodologies simply defining the broad types of taxa found in different soil biomes across environmental gradients? I argue that there is still a way to go in answering these questions, and discuss their relevance in aiding understanding of how soils function. Finally, metagenomic data is presented exploring the potential of high throughput sequencing to answer more relevant questions on both the biogeography of soil diversity and functionality.

STABLE ISOTOPE LABELLING AND TRACKING TO QUANTIFY PLANT-MEDIATED PRIMING OF SOIL ORGANIC MATTER MINERALISATION

Paterson Eric^[1]

^[1]The James Hutton Institute ~ Plant-Soil Ecology ~ Aberdeen ~ United Kingdom

The impacts of labile carbon inputs from plants on soil organic matter (SOM) mineralisation (priming effects) have been long-recognised, but knowledge of the underlying mechanisms remains incomplete. Currently there is increasing appreciation that priming effects are key to soil carbon and nutrient cycles. As such priming effects are central to predicting the carbon-balance of soils in response to environmental change, and the capacity of soils to supply nutrients to support plant productivity. Stable isotope labelling of carbon inputs and isotopic partitioning of soil CO₂ efflux allows direct quantification of priming effects, whilst tracking the fate of labile C in microbial communities provides insights into microbial controls of priming processes. Through application of ¹³C-labelled exudate compounds and by continuous ¹³C-labelling of plants we have quantified priming effects as functions of C-input rates and have demonstrated that these response functions are soil-specific. Quantitative measurement of C-fluxes through microbial communities and dissolved organic carbon in these experiments has supported interpretation of priming mechanisms, suggesting that priming of SOM mineralisation is mediated by specific components of soil microbial communities. The results confirm that fluxes of C out of soil from native SOM are coupled to the supply of labile C to microbial communities and suggest that traditional pool-models based on first-order kinetics will be poorly adapted to capture C-dynamics in soils shifted from equilibrium by environmental or land use change. We suggest that quantitative and mechanistic understanding of priming processes will provide a basis for their incorporation into 'next generation' soil C-models.

S11.07 -2

STOICHIOMETRIC COUPLING OF C AND N TURNOVER REVEALS RHIZOSPHERE PRIMING EFFECTS

Bengtson Per*^[1], Grayston Sue^[2], Barker Jason^[2]

^[1]Lund University ~ Biology - Microbial Ecology ~ Lund ~ Sweden ^[2]University of British Columbia ~ Forestry, Department of Forest Sciences ~ Vancouver ~ Canada

Priming is defined as an increase in decomposition of soil organic matter (SOM) in response to input of easily available C or N. Real priming needs to be distinguished from apparent priming, as apparent priming results from an increased C and N mineralization in response to a higher turnover rate of the microbial biomass, without an accompanying increase in SOM decomposition. Failing to accurately differentiate between real and apparent priming could result in directly opposing interpretations and predictions regarding C sequestration and mineralization. We therefore designed an experiment where two alternative hypotheses were tested, namely that C input in the form of root exudates result in 1. Apparent priming, or 2. Real priming. The hypotheses were tested by estimating the rate of root exudation of seedlings grown in the lab in a ¹³C pulse-chase experiment. The decomposition of SOM at varying C exudation rates was then calculated from the microbial C and N assimilation. The microbial C and N assimilation was highly dependent on the rate of root exudation. However, direct stimulation by root exudates on microbial growth does not provide enough C to explain the increased assimilation. In fact, each mg of C exuded resulted in liberation of 6 mg available C from SOM. Our findings suggest that increased belowground C allocation in the form of root exudates results in real priming and accelerated decomposition of SOM. The estimate is supported by measurements of gross N mineralization, a proxy for SOM decomposition.

Do priming effects vary with changing environmental conditions of temperature and moisture? Here we present data and models of a soil incubation study in the QUASOM project. Soil has been amended with labeled plant litter and has been incubated for 200 days at different combinations of temperature and drying/rewetting cycles. By tracking the total evolution of respired total CO₂ and CO₂ from labeled amendment we study the changes in decomposition of amendment and soil by the different treatments. Drifts of temperature sensitivity of the decomposition rate with time suggest that adaptation of the microbial decomposers is taking place. Consequences for dependence of priming on temperature and moisture will be analyzed using microbial biomass explicit SOM decomposition models.

EFFECT OF PYROGENIC CARBON ADDITION ON GROSS NITROGEN MINERALIZATION AND EXTRACELLULAR ENZYME ACTIVITY

Maestrini Bernardo*^[1], Abiven Samuel^[1], Herrmann Anke M.^[2], Nannipieri Paolo^[3], Landi Loretta^[3], Schmidt Michael W. I.^[1]

^[1]University of Zurich ~ Department of Geography ~ Zurich ~ Switzerland ^[2]Swedish University of Agricultural Sciences ~ Department of Chemistry ~ Uppsala ~ Sweden ^[3]University of Florence ~ Department of Plant, Soil and Environmental Sciences ~ Florence ~ Italy

Fire-derived, pyrogenic carbon (PyC) is produced during vegetation fires, and has been considered as relatively stable in soil. Recent studies, however, question if PyC is as stable as previously thought. Incubation studies indicated an initial rapid carbon mineralization of PyC and release as CO₂. In a field experiment, we also observed that PyC primed the mineralization of native soil organic matter at ambient levels of atmospheric nitrogen deposition, but not at doubled levels of mineral N deposition. We hypothesized that the addition of a complex, C-rich substrate like PyC can reduce the amount of nitrogen available to the soil microbial community. To cope with less available N soil microorganisms will mineralize more soil organic matter, and thus result in increased gross N and C mineralization (i.e. a priming effect). Enzymatic activity would increase according to the theories on complex substrate induced priming effect. According to this theory, substrates with low energy content would favour the growth of K strategists (responsible for the degradation of native soil organic matter), which are expected to allocate more energy to extracellular enzyme production. To test these hypotheses we incubated a mix of soil and highly ¹³C labelled PyC, and measured the PyC-induced priming effect on soil organic matter, gross N mineralization (using ¹⁵N isotope dilution technique) and, the activity of extracellular enzymes responsible for the decomposition of aromatic compounds (phenol oxidase and peroxidase) and for the depolymerization of proteins (protease and amidase). First results will be presented.

PRIMING EFFECTS: INTERACTIONS BETWEEN LIVING AND DEAD ORGANIC MATTER

Kuzyakov Yakov*^[1]

^[1]University of Göttingen ~ Department of Soil Science of Temperate Ecosystems ~ Göttingen ~ Germany

The priming effects – increase or decrease in soil organic matter turnover (measured as changes of CO₂ efflux and N mineralization) after addition of available substrates – is not an artifact of incubation studies, but is a natural process sequence in the rhizosphere and detritusphere that is induced by pulses or continuous inputs of fresh organics. Recent publications have shown that priming effect (PE) results from interactions between living (microbial biomass) and dead organic matter and commonly occurs in most plant–soil systems.. The intensity of turnover processes in such hotspots as rhizosphere and detritusphere is at least one order of magnitude higher than in the bulk soil. Various prerequisites for high-quality PE studies will be outlined: calculating the C budget; analysis of the dynamics of released CO₂ and its sources; linking C and N dynamics with microbial biomass changes and enzyme activities; evaluating apparent and real PEs; and assessing PE sources as related to soil organic matter stabilization mechanisms. Approaches for identifying priming, based on the assessment of more than two C sources in CO₂ and microbial biomass will be proposed. Future studies should evaluate directions and magnitude of PEs according to expected climate and land-use changes and the increased rhizodeposition under elevated CO₂ as well as clarifying the ecological significance of PEs. The conclusion is that PEs – the interactions between living and dead organic matter – should be incorporated in models considering microbial biomass as an active driver of C and N turnover.

**DOES THE MINERALIZATION OF ERODED LAND-BORN C IN INLAND WATERS
ACCELERATED BY PRIMING EFFECT?**

Guenet Bertrand*^[1]

^[1]CNRS ~ LSCE ~ Gif Sur Yvette ~ France

In the last decade, several studies questioned the becoming of Terrestrial Organic Matter, such as transported soils, in aquatic systems. Soil Organic Matter (SOM) is classically considered as more recalcitrant than autochthonous organic matter. However, SOM contributes largely to carbon budget of aquatic ecosystems, mainly via the incorporation of soil organic carbon by bacteria. Furthermore, whether transported SOM is a C-sink through burial in aquatic sediments or a C-source due to rapid outgassing is still strongly debated. In soil sciences, it is now well established that presence of Labile Organic Matter (LOM), such as glucose or roots exudates, can influence SOM mineralization, this phenomenon being called Priming Effect (PE). Despite the abundance of LOM (e.g. transparent exo-polymers or algal exudates) in aquatic ecosystems, occurrence of PE during SOM processing in these ecosystems has almost never been evoked. In this study, we measured how quickly Soil Organic Matter (SOM) sampled from cropland, meadow, forest and bare fallow was mineralized in shallow and agitated aquatic systems as compared to 'classical' mineralization within soil horizons. We show that the most important factor controlling the C fluxes was the ecosystem where soils were sampled. Then, aquatic conditions increase SOM mineralization by 91% due to an important increase during the first days. Glucose addition simulating fresh LOM exudation by phytoplankton, increased by 18.7% the SOM mineralization in water. The amount of CO₂ derived from SOM mineralization emitted by aquatic systems might depend upon SOM aggregates stability, modulated by the availability of LOM and nutrients.

One of the more theoretical questions about the current approach to assessing the risk of transport through soil of bacteria originating in organic waste is the significance of micro- versus macro-scale parameters. Assessments at different scales and test conditions can be integrated to evaluate the level of mechanistic or stochastic detail that should be adequate to describe risk. Stochastic, black box risk analyses at large scales regularly show it is possible for risk to be linked to macro-scale parameters. Field research across soil types appears to suggest that soil parameters (e.g. matrix properties), such as soil pores size, geometry and continuity, dominate the control of transport. On the other hand, mechanistic assessments at small scales indicate the capacity of microbial cells to interact with surfaces and among each other in flocs mediated by the organic material. In the presence of organic waste materials, however, the variable charge on bacterial cells may be less critical for cell retention. Thus it is not certain that detailed mechanistic approaches are significantly useful for estimating bacterial transport under field conditions or if soil pore heterogeneity parameters, even at macro-scale, may be singly sufficient to estimate risk. We integrated results from experiments carried-out ranging from centimeter to field scales. Results suggest that 1) results inferred from a given spatial scale cannot be necessarily directly transferred across a range of spatial scales and 2) cross-scale experimental integration may be critical for the development of coherent risk assessment parameters.

The main objective of this study was to evaluate the combined effects of grain size and pore water velocity on the transport in water saturated porous media of three waterborne fecal indicator organisms (Escherichia coli, MS2, and FX174) in laboratory-scale columns packed with clean quartz sand. Three different grain sizes and three pore water velocities were examined. The attachment behavior of Escherichia coli, MS2, and FX174 onto quartz sand was evaluated. The mass recoveries of the three biocolloids examined were shown to be highest for Escherichia coli and lowest for MS2. However, no obvious relationships between mass recoveries and water velocity or grain size could be established from the experimental results. The observed mean dispersivity values for each sand grain size were smaller for bacteria than coliphages, but higher for MS2 than FX174. The single collector removal and collision efficiencies were quantified using the classical colloid filtration theory. Furthermore, theoretical collision efficiencies were estimated only for E. coli by the Interaction-Force-Boundary-Layer, and Maxwell approximations. Better agreement between the experimental and Maxwell theoretical collision efficiencies were observed.

FORCES DRIVING ADSORPTION OF TRANSGENIC INSECTICIDAL CRY PROTEINS TO ORGANIC MATTER

Sander Michael^[1], Michael Madliger^[1], Jeanne E. Tomaszewski^[1], Joel A. Pedersen^[2], René P. Schwarzenbach^[1]

^[1]ETH Zurich ~ Department of Environmental Sciences, IBP ~ Zurich ~ Switzerland ^[2]University of Wisconsin ~ Departments of Soil Science and Civil & Environmental Engineering ~ Madison ~ United States

Adsorption to natural organic matter is a key process affecting the environmental activity, stability, and transport of proteins, including enzymes, pathogenic prions, and insecticidal Cry proteins expressed by transgenic Bt crops. Despite its importance, protein adsorption to organic matter has received little attention. Here, we assess the adsorption of Cry1Ab, a commercially important Cry protein, to a large set of humic and fulvic acids as a function of solution pH and ionic strength I. Adsorption was measured by two in situ surface techniques, quartz crystal microbalance with dissipation monitoring and optical waveguide lightmode spectroscopy. Cry1Ab adsorption to negatively charged HS increased with decreasing I, also at pH above the isoelectric point of Cry1Ab (IEP= 6). This I-dependence suggests patch-controlled electrostatic attraction (PCEA), by which net negatively charged Cry1Ab was oriented with positively charged surface patches towards the HS. Molecular modeling of Cry1Ab, which shows a highly non-uniform surface charge distribution, supports the PCEA adsorption mechanism. Cry1Ab adsorption to HS decreased and desorption from HS increased with increasing pH, consistent with attenuation of PCEA due to the concomitant decrease in positive surface charge. At any given pH and hence Cry1Ab charge, adsorption varied considerably between the tested HS and was found to increase with decreasing HS polarity, suggesting that adsorption also had a strong contribution from the hydrophobic effect. Cry1Ab adsorbed to a selected humic acid retained full insecticidal activity in diet incorporation bioassays, demonstrating that adsorption did not result in irreversible structural changes of the Cry1Ab.

Transmissible spongiform encephalopathies (TSEs), or prion diseases, are a family of neurodegenerative disorders caused by a pathogenic conformational isomer of the mammalian prion protein (PrP). Due to the extreme stability of these misfolded proteins, dubbed PrPTSE, their release into the environment through alimentary or urinary shedding or carcass decomposition has been implicated in the spread of TSEs in some wild and domestic animal species. Understanding the forces that govern the interactions of PrPTSE with environmental surfaces will improve our understanding of the fate of infectious prions in soil environments. Heretofore, the forces governing the attachment of PrPTSE to environmental surfaces have been poorly understood. Here, we report the results of a study examining the attachment of PrP to charged mineral surfaces under diffusion limited attachment conditions. Combining data from a diverse group of techniques, including electron microscopy, atomic force microscopy (AFM), quartz crystal microbalance with dissipation monitoring (QCM-D) and optical waveguide lightmode spectroscopy (OWLS) has allowed us to begin to form a molecular level understanding of the interactions between these types of surfaces and infectious prions. Results of these experiments show that solution pH and ionic strength strongly influence the rate and extent of prion attachment to charged mineral surfaces, consistent with a dominant role for electrostatic interactions and protein aggregation state in PrPTSE attachment.

We have compared the catalytical activity of fungal phosphatase in solution and after adsorption on either kaolinite or montmorillonite as a function of purity and fractionation of raw extracts. Most measurements were made over a range of pH values (3 – 6). Protein containing solutions were purified using an Amicon filter and fractionated in a fast-flow chromatograph with a hydrophobic column. Catalytic activity was well preserved in the adsorbed state. Removal of low molecular weight impurities by diafiltration had no effect on the pH- dependence of activity in solution, nor on affinity for mineral surfaces nor the preservation of catalytic activity in the adsorbed form. The presence of proteins or protein-like molecules, concentrated in the fraction not retained on the hydrophobic column competed with phosphatases for adsorption, leading to decreased affinity for the mineral surfaces but had no effect on activity after adsorption. Protein-like substances were absent from fractions eluted from the hydrophobic columns. Phosphatase in these samples showed enhanced activity after adsorption. Comparison with the effect of adding another protein to these samples, and the concentration effect of phosphatases leads us to suggest that enhanced activity is due to dimerisation on the mineral surface. Dimerisation is prevented when nearest neighbours are not phosphatases..

The power of Artemisia annua L. to counter the pandemic disease malaria has been increasingly acknowledged in the last century, as this herb is the only source of the anti-malarial drug artemisinin. A. annua cultivation has expanded and the impact to soil and water organisms is presented. Artemisinin in leaves and distribution in soil was monitored underneath source plants. The effect on bacterial growth in an A. annua plantation was compared to an intercrop by using the 3H-Leucine incorporation and agar-plate counts. Artemisinin was found more than 2 m from the plant and up to a soil depth of 90 cm with a maximum concentration of 449 µg/kg. Soil-artemisinin concentration changed during the growing season with max leave content 0.019±0.002% and 0.035±0.001% of leave DW at 2 and 18 weeks, resp. Bacterial growth was reduced by 44% in the soil under A. annua plantation compared to control soil, in soil planted with the intercrop the reduction accounted for only 21%. Agar plate counts suggested effects on bacterial community composition and revealed also that the bacterial community is able to adapt to continuous artemisinin input. Artemisinin is leaching and potentially appears in groundwater and surface waters. A high artemisinin input to soil during growing season could impair bacterial growth and community composition and thus, humble soil quality. A large-scale cultivation of A. annua should implement alternative management strategies like intercropping and distances to vulnerable surface waters.

IMPACT OF PHYSICOCHEMICAL PROPERTIES AND MICROBIAL COMMUNITY STRUCTURE ON THE SURVIVAL OF *E. COLI* O157:H7 IN EASTERN CHINA SOILS

Wang Haizhen^[1], Xu Jianming^{*[1]}

^[1]Zhejiang University ~ Institute of Soil and Water Resources and Environmental Science, Zhejiang Provincial Key Laboratory of Subtropical Soil and Plant Nutrition ~ Hangzhou ~ China

In the present study, survival of E. coli O157:H7 in 14 soils collected from different geographic zones of eastern China was investigated. Bacterial, archaea, and fungi community structures from these soils were investigated using 454 pyrosequencing technique. The phospholipid fatty acids (PLFAs) in soil bacteria were identified by GC fitted with a MIDI Sherlocks microbial identification system. The survival experiments were conducted at 21±1 °C with a soil moisture content of 40% water holding capacity, and the initial cell concentration was about 10⁶ CFU/g soil. Survival data were modeled using Weibull model, and the calculated time points (td) when the cell concentration went below the detection limit (100 CFU/g soil) were correlated to the soil properties. E. coli O157:H7 survival time in days (td) was between 1.4-26 days. The longer survival of E. coli O157:H7 was observed in northeastern Chinese soils than in southeastern Chinese soils. Results showed that td was positively correlated with soil assimilable organic carbon (AOC), silt content, microbial biomass carbon (MBC), and the abundance of Actinobacteria and bacterial PLFAs, but negatively with the abundance of fungal PLFAs. The abundance of archaea had no significant effect on E. coli O157:H7 survival. Stepwise multiple regression analysis revealed that the survival of E. coli O157 was significantly enhanced by soil AOC and Actinobacteria, and significantly suppressed by clay content. Overall, the survival of E. coli O157:H7 in soils was mainly controlled by AOC, soil texture, and the interactions between indigenous microbial communities and the introduced pathogen.

Interactions among soil and soil enzymes are important because adsorption phenomena have a deep influence on enzymes catalytic activity. However little knowledge is available about the nature of interactions of a given enzyme in a specific soil. To elucidate this we performed a series of extractions using different amounts of desorbing protein. Six soils were used and five enzymatic activities were measured: arylsulfatase, beta-glucosidase, leucine-aminopeptidase, acetate-esterase, alkaline phospho-monoesterase. Increasing desorbing protein amount increased extraction yield, but the response was very different for each enzyme. Different minimal amounts of desorption protein were necessary to detect enzymatic activities in the extract, depending on the soil and enzymatic activity. Dose-response effect was either linear or curvilinear and was both soil- and enzyme-specific. As a consequence, a plateau was reached only in some cases, even though the amount of protein used was up to about 30% of soil by weight. These results highlight that: i- a significant part of soil enzymes can be easily desorbed and; ii- interactions of different soil enzymes in a specific soil can be unveiled with this simple approach.

Soil organic phosphorus (P) has to be enzymatically hydrolysed to orthophosphate before it can be taken up by plants. Potentially hydrolysable organic P can be measured by addition of phosphohydrolases to soil suspensions and extracts, followed by colorimetric measurement of released orthophosphate. The objectives of this study were (i) to characterize the substrate specificity of commercially available enzyme preparations using model substrates, (ii) and to measure the release of orthophosphate from soil water suspensions and extracts in order to characterize the availability of organic P in presence or absence of solid particles. Two Swiss grassland soils with high organic P and low orthophosphate concentrations were treated with seven different enzyme preparations, including acid and alkaline phosphomonoesterases, phytases and a nuclease. Based on the substrate specificity, P released from simple monoesters, inositol-hexakisphosphate and DNA could be distinguished. In all cases, more orthophosphate was released from soil suspensions than from filtered extracts. Hydrolysable organic P compounds in suspension ranged in the order DNA > inositol-hexakisphosphate > simple monoesters for one soil and simple monoesters > inositol-hexakisphosphate > DNA for the other soil. For the first soil, this contrasts with the typically low proportions of DNA and the dominance of simple and multiple monoesters in alkaline soil extracts as determined by ³¹P NMR. Thus, the addition of enzymes to soil suspensions can be a useful tool to characterize bioavailable organic P, and the comparison of suspensions and extracts helps to locate the hydrolysable substrate.

The mineralisation of soil organic matter is the main source for plant-available nitrogen in forest soils and is dependent on litter composition, its depolymerisation rate and the soil type. To trace and to quantify the fate of nitrogen in different soil pools through litter decomposition, 15N labelled litter was deposited on the soil of three 2 m x 2 m plots after removing fresh non-decomposed litter in April 2008. The studied site is characterized as a Rendzic Leptosol in a beech forest (Fagus sylvatica) with humus type mull near Tuttlingen (Swabian Jura, Germany). The isotopic nitrogen composition of the bulk soil and the soil fractions were monitored the following three years through several harvests of the litter and the Ah horizon (0-10 cm). A combined density and particle-size fractionation with sodium polytungstate and ultrasonic dispersion allowed the separation of the free light fraction, occluded organic matter and organo-mineral associations. Subsequently, light and heavy soil fractions, bulk soil and litter samples were measured for 15N concentration. Measurements of 15N concentration showed a first increase in the free light fractions after 140 days and a time-delayed recovery in the occluded light fractions, indicating a slow aggregate turnover. Furthermore, the observed results indicate a quick transfer of 15N-enriched compounds from litter to the clay fractions, where the enrichments per soil unit exceeded the concentrations of the light fractions already after 140 days. The high concentrations of 15N in the clay fractions revealed a dominant role of organo-mineral associations for the stabilization of nitrogen.

^[1]Museum National d'Histoire Naturelle ~ LMCM ~ Paris ~ France ^[2]INRA ~ Biogéochimie des Ecosystèmes Forestiers ~ Champenoux ~ France

Soil organic matter represents the major source of nitrogen in natural ecosystems: plant productivity strongly depends on the rate of nitrogen release by decaying litter and microbial recycling, two processes governed by interactions within the soil matrix. ¹⁵N labelling combined with Isotope Ratio Mass Spectrometry has been very useful to assess the fate of litter-derived nitrogen over time and its uptake by plants. The complimentary use of nano-scale secondary ion mass spectrometry (NanoSIMS), by tracking isotopic label at the micron scale, shed new lights on the influence of organomineral interactions on N dynamics. We present results from the NanoSIMS imaging of ¹⁵N labelled soil microaggregates recovered from short and long term incubations. We studied a soil incubated for eight hours with ¹³C¹⁵N glycine. Images indicate a fast utilization of the soluble glycine by microbes revealed by the spatial decoupling of ¹³C and ¹⁵N locations in organic matter attached to soil particles. The distribution of the label is not correlated with the particles typology, and is likely driven by the location of microbes in the soil matrix. We also imaged some soil particles collected from a decadal incubation of ¹⁵N labelled litter. The label derived from the litter was found as submicron sized clusters. Though these clusters are likely not preserved vegetal debris, they contain OM that has not been heavily reprocessed by microbes because an intense recycling would have diluted and spread the isotopic signal. Here, association of OM with a complex mineral structure may have hampered microbial activity.

In soil, organic, inorganic and biological constituents are contacting each other and forming biogeochemical interfaces upon which important processes for the ecosystem act. This study tries to gain insights into the highly diverse, complex microbial communities in soil. Since the comparison of microbial communities from natural soils is problematic, different artificial soils with a known mineral composition were used. To each artificial soil the same microbial community extracted from a natural Cambisol and autoclaved manure as organic matter was added. They were incubated under constant environmental conditions up to 18 months. The influence of mineral composition and charcoal on the establishment of microbial communities was studied. Total community DNA was extracted and the 16S rRNA gene and ITS amplicons for Bacteria or Fungi, respectively, were used in DGGE. The DGGE data showed that soil minerals and charcoal influence microbial community structure in short and long term. Pyrosequencing of day 90 samples confirmed a striking effect of charcoal on the bacterial community and several discriminative taxa were identified between the artificial soils. Furthermore, the response of microbial communities at biogeochemical interfaces to phenanthrene was explored. Therefore, one-year old artificial soil samples were spiked with phenanthrene (2 g/kg) and incubated for another 70 days. Cultivation and DGGE showed a strong response of Bacteria, Actinobacteria, Alphaproteobacteria and Betaproteobacteria to phenanthrene spiking whereas no effect was seen for Fungi.

In conclusion, it was shown that mineral composition, charcoal and phenanthrene are important factors shaping the composition of microbial communities established in artificial soils.

Soil respiration constitutes a major source for carbon dioxide release to the atmosphere, but metal-organic complexation may delay soil microbial activity. Phenolic compounds, e.g. gallic acid (GA), are ubiquitous in soil, originated from natural or anthropogenic inputs of organic carbon (OC), and therefore a common substrate for microbial degradation. Aqueous solutions of gallic acid (GA) (0.050 mM) were added with increasing concentrations of FeCl₃•6H₂O (0–0.4 mM). UV-visible spectrometry demonstrated the complexation of Fe(III) by gallic acid and fluorescence emission spectra were collected to characterize the formation of such GA-Fe complexes. Spectral attenuation (quenching) determined by excitation-emission matrix fluorescence spectroscopy confirmed the formation of metal-organo complexes. The spectrometric analysis demonstrated the formation of complexes of Fe(III) with gallic acid by Fe binding to the phenolic groups, but moreover provided information on the types of metal-organic complexes, which depended on Fe(III) concentration. The formation of metal-organo complexes was related to the alteration of the enzymatic oxidation rate of GA by the enzyme tyrosinase (L-DOPA was used as a control), determined by spectrophotometric measurement at 300 nm. Overall, structural changes to the gallic acid molecule due to metal complexation inhibited its enzymatic oxidation. Similar processes might inhibit degradation of soil organic matter.

TO WHAT EXTENT CLAY MINERALS AFFECT SOIL AGGREGATION? A QUANTITATIVE APPROACH BASED ON X-RAY PATTERNS MODELLING

Fernandez-Ugalde Oihane^[1], Barré Pierre^[1], Hubert Fabien^[2], Virto Iñigo^[3], Chenu Claire^[4], Ferrage Eric^[2], Caner Laurent^[2]

^[1]Ecole Normale Supérieure ~ Laboratoire de Géologie ~ Paris ~ France ^[2]Université de Poitiers ~ Hydrasa Laboratory ~ Poitiers ~ France ^[3]Universidad Pública de Navarra ~ Ciencias del Medio Natural ~ Pamplona ~ Spain ^[4]AgroParisTech ~ BIOEMCO Laboratory ~ Thiverval-Grignon ~ France

Aggregation is a key process for soil functioning as it influences C storage, vulnerability to erosion and water holding capacity. If the influence of soil C content or tillage on aggregation has been documented, little is known about the role of soil mineralogy. The aim of this study is to determine quantitatively if different clay-size minerals of a temperate soil contribute differently to aggregation and if their contribution is modulated by soil management. We compared aggregate-size distribution and C content of mouldboard-ploughing (tilled yearly), minimum-tillage (tilled every 4 years) and grassland in the 0-5 cm from a long-term trial in a silt loam soil in Versailles (France). For each size-class, fraction <2 µm was separated for identification and quantification of minerals by modelling X-ray diffractograms using the Sybilla software. C content was lower in the mouldboard-ploughing treatment than in the two others. The proportion of large-macroaggregates (500-5000 µm) was greater in minimum-tillage and grassland; while microaggregates (50-250 µm) showed greater proportions in mouldboard-ploughing. In the three treatments, microaggregates had the greatest amount of clay, with preferential accumulation of smectite. In grassland, clays from all aggregated fractions showed more smectite than free-clay fraction. The results indicate that swelling clays contributed particularly to the microaggregates dynamics. Their contribution to aggregation was lower for bigger aggregate sizes where the influence of organic matter and fungal hyphae was preponderant. Moreover, it was observed that cultivation reduced selection of swelling clays in aggregates which makes them more vulnerable to erosion and alters their physico-chemical functions.

ROCK FLOUR FERTILIZATION: NEW PERSPECTIVES FOR AN ANCIENT TECHNIQUE.

Manning David*^[1], Bergsma Huig^[2], Bleken Marina^[3]

^[1]Newcastle University ~ Civil Engineering & Geosciences ~ Newcastle upon Tyne ~ United Kingdom ^[2]ARCADIS Nederland BV ~ Geochemistry ~ Apeldoorn ~ Netherlands ^[3]Norwegian University of Life Sciences ~ Plant & Environmental Sciences ~ Ås ~ Norway

In October 2011 world population reached 7 billion. Agricultural production is under increasing pressure, and valuable cropland is suffering increased soil degradation. Solid solutions are needed and cannot be found by improvement of existing cropping techniques alone. To achieve sustainable progress we have to broaden our understanding of soil fertility, combining and reevaluating several disciplines of soil science. Soil mineralogy is fundamental when it comes to soil fertility. Soil minerals are the backbones of agriculture providing nutrients, shelter for various soil life forms, preserving organic matter, and reducing atmospheric CO₂ levels. High crop production and large scale application of fertilizer and soil conditioners have made us think of soil minerals as an inert substrate rather than particles that can be exhausted. Loss of mineral function relates to problems including rapidly disappearing (sub)tropical forests, loss of soil organic matter and nutrient deficiencies in moderate climate zones. Rock flour fertilization represents a viable option to encounter these problems. Rock forming minerals can protect, replace and improve soil mineralogy. Considered so far mainly for nutrient delivery, other merits will prove to be as valuable in the years to come. Rock flour should be regarded as a supplemental instead of a competing technique. However, before introducing it as a tool for soil restoration, more insight is needed regarding the overall response of soil performance to different types of rock flour.

V.M. GOLDSCHMIDT AND COLLABORATORS - UNKNOWN ROCK POWDER PIONEERS – A REVIEW

Heim Michael*^[1], Bleken Marina Azzaroli^[1]

^[1]Norwegian University of Life Sciences ~ Dept of plant and environmental sciences ~ Aas ~ Norway

Experiments with Norwegian rock powder started during WW1, in consequence of K-fertilizer shortage, under the lead of renowned geochemist V.M. Goldschmidt. Theory and chemical tests indicated that, under northern climatic conditions, biotite-mica and not as generally accepted K-feldspar was the principal primary source of K to plants (Goldschmidt and Johnsen 1922). To test this, the most extended Norwegian 'rocks for crops' experiments ever – concerning geological materials used, soil types, geographical distribution and duration – were done from 1922 to 1935, in collaboration with the Agricultural College of Norway (Cranner 1922, Solberg 1928, Retvedt 1938). Fundamental to these investigations was Goldschmidt's selection and mineralogical control of applied rock powders, and their duration (up to 9 years) to document long time effects, important aspects often missing in later experiments. These outstanding field experiments with K-bearing rock powders, showed that under northern conditions: 1)Biotite and phlogopite (Mg-biotite) gave highest yields, occasionally exceeding those of soluble fertilizer (KCl), especially in long time experiments. K-feldspar and muscovite (sericite) had little effect, 2)Rock powders showed best effects in peat soil, low effects in clay soils 3)A long-lasting effect, reducing the need for frequent application was observed. Fine grained fractions reacted fast, coarse ones slower but longer and 4)Surficial application of biotite/phlogopite had good effect on perennial crops like grass etc The results published locally and in Norwegian, have remained largely unknown. The aim of this review is to make these ground-breaking investigations known internationally, critically considering their relevance almost 100 years after their initiation by Goldschmidt.

DECREASING CO₂ EMISSION IN AGRICULTURE BY USING ROCK FLOUR AS AN ALTERNATIVE FOR AGRICULTURAL LIME AND POTASSIUM FERTILISERS

Rietra Rene*^[1]

^[1]Wageningen University and Research Centre ~ Alterra, Soil Science ~ Wageningen ~ Netherlands

Rock flours are natural resources that have been used since a long time as plant nutrient sources and soil conditioners. Although rock flour clearly has positive effects on the soil pH the efficiently compared to lime is not well known, and a significant effect on plant growth has only been shown for a limited type of rock flours that can deliver potassium. The application of basic rock flours has received new attention as it has potential to remediate CO₂ emission from agriculture. Rock flour has the potential to be an alternative for agricultural lime, which according to IPCC causes CO₂ emissions and it has potential to deliver potassium with low energy (CO₂) costs. I will present results from a field trial with grass where we have added various rates of olivine to a soil and a rock flour, and compared this to using conventional fertilisation with kieserite and lime. Olivine is used here as a model for basic silicates. During two years the effects on soil and grass have been determined. Besides using rock flour as an alternative for agricultural lime it has been suggested that rock flours such as olivine might be used to bind CO₂ from the air (Krijgsman and Schuiling, 2006; Köhler et al, 2010), although experimental proof for this is lacking. Therefore I will present the experimental results of using olivine in lysimeters during two years, and its effect on bicarbonate concentrations in the leachate.

K-SILICATE MINERALS AS A SOURCE OF K FOR LEEKS (*ALLIUM PORRUM*) IN SANDY SOIL

Mohammed Othoman Safiya^{*[1]}, Manning David^[2], Gray Neil^[2], Brandt Kirsten^[1]

^[1]Newcastle University ~ Agriculture, Food & Rural Development ~ Newcastle upon Tyne ~ United Kingdom ^[2]Newcastle University ~ Civil Engineering & Geosciences ~ Newcastle upon Tyne ~ United Kingdom

*Potassium is one of the most important plant nutrients in agriculture; it is essential for plant growth, required in large amounts, rapidly lost from agricultural soils, and sources are limited. The potential value of K silicate minerals as a novel source of K was assessed using leek (*Allium porrum* var. Oarsman F1). Leek seedlings were grown with 3 plants per 1 kg pot artificial soil under controlled climate conditions and controlled appropriate soil water potential. Potassium chloride (63% K₂O equivalent) was used as a positive control, and silicate mineral sources of K were feldspar (microcline; 11% K₂O) and biotite (9% K₂O), with application rates 138 – 550 mg K/kg soil. Soil physical and chemical characteristics were analysed. Crop growth was assessed by measurement of plant neck diameter as well as fresh and dry mass. Leek growth rates (increase in neck diameter) for an application of 550 mg K/kg soil were: K-free control: 0.11 mm/week, microcline 0.19 mm/week, biotite 0.42 mm/week and KCl 0.49 mm/week. These results reflect the expected slow release of K from microcline, demonstrating its potential as a long-term source of K. Biotite appears to be as effective as KCl as source of K, due to its high cation exchange capacity. Together with other experiments using natural soil and/or other K-sources and doses, the study showed that measurement of leek neck diameter is an excellent indicator of K-dependent growth, due to an almost linear increase for 6 weeks or more in all treatments.*

DAVID JENKINSON AND THE SOIL MICROBIAL BIOMASS

Brookes Philip*^[1], Powlson David^[1]

^[1]Rothamsted Research ~ Sustainable Soils and Grassland Systems ~ Harpenden ~ United Kingdom

Professor David Jenkinson's pioneering idea of studying the soil microorganisms as a single unit, or black box, has massively influenced soil science, as the number of related papers, published worldwide, has shown. The original method based upon CHCl₃ fumigation, and published with David Powlson in 1976, was a bioassay. It stood the test of time until 1985, when the first of a number of fumigation based procedures, with Phil Brookes, converted the original method to a chemically based procedure (Fumigation Extraction) which had many advantages. The biomass methods were much more than simply procedures to characterize soils. They opened up many new research areas and are used all over the world in research into carbon and nutrient dynamics, mathematical modeling, microbial survival, soil quality and much more.

^[1]University of Florence ~ Department of Plant Soil and Environmental Sciences ~ Florence ~ Italy ^[2]University of Florence ~ Department of Plant Soil and Environmental Sciences ~ Florence ~ Italy ^[3]University of Florence ~ Department of Plant Soil and Environmental Sciences ~ Florence ~ Italy ^[4]University of Florence ~ Department of Plant Soil and Environmental Sciences ~ Florence ~ Italy ^[5]University of Florence ~ Department of Plant Soil and Environmental Sciences ~ Florence ~ Italy

Definition of the soil microbial biomass (SMB) concept has allowed great progresses in the study of the soil organic matter (SOM) turnover, and allowed to identifying and quantifying the microbial the C, N, P and S pools. Among the most relevant advances brought by the SMB concept there is the fact that microbial C, N, P and S pools, which represents 1-4% of the total organic pools, play a relevant ecological role because undergo faster biogeochemical cycles than the non cellular soil OM and the SMB acts as both source and sink of nutrients for plants. The SMB seen as black box containing interactive microbial species has been successfully applied in soil agro-ecology as early indicator of soil pollution ecological changes, and modelling of SOM dynamic. The fast development of the so called 'omic' approaches allowed the identification of a large number of species and the study of gene expression of selected soil microbial species. Among them, soil proteomics aims at identifying proteins expressed in the soil microbial communities with key ecological functions, through the study of the protein expression profile of living organisms. Soil proteomics has been mainly studied by non-soil scientists such as molecular microbiologists and protein chemists, and consequently the illuminating concept that the microbial biomass only contains at most 4% of soil total N has been neglected, drawing probably misleading conclusions. As proteins theoretically account for 50% of SMB, advances in soil proteomics may shed new light on the protein turnover and N stabilization in soils

^[1]Chiba University ~ Graduate School of Horticulture ~ Matsudo ~ Japan ^[2]Chiba University ~ Graduate School of Horticulture ~ Matsudo ~ Japan ^[3]Lambung Mangkurat University ~ Faculty of Agriculture ~ Banjarbaru ~ Indonesia ^[4]University of Palangka Raya ~ Faculty of Agriculture ~ Palangka Raya ~ Indonesia ^[5]University of Palangka Raya ~ Faculty of Agriculture ~ Palangka Raya ~ Indonesia ^[6]University of Palangka Raya ~ Faculty of Agriculture ~ Palangka Raya ~ Indonesia ^[7]Hokkaido University ~ Graduate School of Agriculture ~ Sapporo ~ Japan

Huge amount of greenhouse gases such as carbon dioxide (CO₂) and nitrous oxide (N₂O) has been emitted in tropical peat soil. Microbial biomass is one of the important factors to understand CO₂ and N₂O emission which is derived from microbial reactions. However, interrelationship between greenhouse gas emission and microbial biomass is not clear. This study was conducted to quantify the microbial biomass in tropical peat soil and clarify the interrelationship among microbial biomass, CO₂ and N₂O emission. Field observation was carried out near Palangka Raya in Central Kalimantan, Indonesia from July 2009 to March 2011. CO₂ and N₂O fluxes were measured using the closed chamber method. Soil samples were collected to determine soil properties including SOC (soluble organic carbon) content. Fumigation-extraction method was applied to measure microbial biomass carbon (MBC) and microbial biomass nitrogen (MBN). MBC and MBC/SOC ratio showed positive linear relationships with CO₂ flux in the forest land ($r=0.74^{**}$, and $r=0.93^{**}$, respectively; ** : $P<0.01$), but not in the cropland. However, it was found that CO₂ flux in cropland was correlated with precipitation and high N₂O flux ($r=0.90^{**}$, and $r=0.81^{**}$). MBC/MBN ratio also showed significant positive relationships with CO₂ flux in natural forest ($r=0.92^{**}$) and burned forest ($r=0.76^{*}$; * : $P<0.05$). These results indicated that CO₂ emitting process may be different in forest area and cropland. C/N ratio of microbial biomass may influence CO₂ emission in forest area. However, CO₂ emission in cropland is controlled by different factors such as precipitation which will enhance N₂O emission.

^[1]Russian Academy of Sciences ~ Institute of Physicochemical and Biological Problems in Soil Science ~ Pushchino ~ Russian Federation ^[2]Max Planck Institute for Biogeochemistry ~ Biogeochemical Processes ~ Jena ~ Germany

*Extending drought periods as a consequence of global warming affect both the amount and the activity of heterotrophic microorganisms in soil. The studies of drought effect on the decomposition of soil organic matter (SOM) which is microbially mediated still show controversial results mainly due to separated research approaches which do not consider the soil – plant system as a whole. We would like to discuss the results obtained within the QuaSOM experiment (Max Planck Institute for Biogeochemistry Jena, Germany) where continuous ¹³C- CO₂-labeling was applied during vegetation of peppermint (*Mentha piperita* L.) under deficit and optimal moisture regimes. The partitioning of plant-originated and SOM-originated carbon in heterotrophic respiration and in microbial biomass will be related to the changes in the microbial growth parameters and enzymes kinetics. The drought effect on temperature sensitivity of the enzymes responsible for the decomposition of SOM-compounds of different availability will be compared in the rhizosphere of peppermint versus bulk soil. The effect of vegetation on cycling of organic matter in soil will be considered for the contrasting moisture regimes. The changes in carbon sequestration potential due to priming effects caused by repeated drying – rewetting events will be evaluated for the short term time scale.*

MINERALIZATION-IMMOBILIZATION OF SULFUR IN A SOIL DURING DECOMPOSITION OF CROP RESIDUES VARYING BY THEIR BIOCHEMICAL QUALITY AND S CONTENT

Recous Sylvie^{*[1]}, Hamid Niknahad-Gharmakher^[2], Séverine Piutti^[3], Jean-Marie Machet^[4], Emile Benizri^[5]

^[1]INRA ~ UMR 614 Fractionnement des Agroressources et Environnement ~ Reims ~ France ^[2]Gorgan University of Agricultural Sciences and Natural Resources ~ Rangeland management Department ~ Gorgan ~ Iran, Islamic Republic of ^[3]INPL-ENSAIA ~ Laboratoire Agronomie et Environnement ~ Vandoeuvre-lès-Nancy ~ France ^[4]INRA ~ Unité Agro-Impact ~ Laon ~ France ^[5]INPL-ENSAIA ~ Laboratoire Sols et Environnement ~ Vandoeuvre-lès-Nancy ~ France

Sulfur (S) is an essential element for plants and animals. Because elements combine in soil organic matter, the C and S cycles are interdependent. The recycling and decomposition of plant residues can be an important source of available sulfate in soils, compared to the soil available S, which requires prediction for adequate sulfur management in agricultural soils. The aims of our study was to investigate (i) the effect of soil sulfate availability on crop residue decomposition and associated S mineralization and (ii) the relationships between plant residue quality (both plant biochemistry and S content) and S and C mineralization. Therefore in a first soil incubation experiment we examined the effect of initial soil sulfate content on decomposition by adding sulfate at two different concentrations in a presence of a single rate of rapeseed straw addition in a loamy soil. Then in a second experiment, we used four other residues of different biochemical compositions and S contents (wheat straw, tall fescue, mustard and beech leaves) to assess the relationship between S mineralization and plant residue composition. Net C and S mineralization were measured continuously during a 175-day incubation at 20°C and gross S mineralization and immobilization were quantified using ³⁵S soil labeling applied as pulses during incubation. The data obtained allowed to quantify S fluxes during plant residues decomposition, to discuss the relationships between kinetics of gross and net S mineralization, C dynamics, residues quality and their decomposition, and between net S mineralization and the C/S of plant residues.

PHOSPHORUS, CARBON AND NITROGEN INTERACTIONS IN TROPICAL GRASSLANDS ON HIGHLY WEATHERED SOILS

Oberson Astrid*^[1], Maike Nesper^[1], Django Hegglin^[1], Steve Fonte^[2], Idupulapati M. Rao^[2], Bertha Ramirez^[3], Jaime Veilasquez^[3], Else Bünemann^[1], Emmanuel Frossard^[1]

^[1]ETH Zurich ~ Institute of Agricultural Sciences, Group of Plant Nutrition ~ Lindau ~ Switzerland ^[2]Centro Internacional de Agricultura Tropical (CIAT) ~ Soil Ecology ~ Cali ~ Colombia ^[3]Universidad de la Amazonia ~ Agroforestry ~ Florencia ~ Colombia

The highly weathered pasture soils of the deforested areas of tropical South America usually have low phosphorus (P) contents which can strongly limit soil functions associated with the cycling of carbon (C) and nitrogen (N). Although the importance of P deficiency in pasture degradation has been recognized, knowledge on stoichiometry of C, N and P along pathways of nutrient cycles of pastures with different botanical composition and productivity is limited. We realized a case study on farms in Colombia. Our objectives were to determine whether: i) P availability is lower in degraded than productive pastures; ii) introduction of legumes increases P availability through enhanced biological P cycling; iii) pasture types affect C:N:P ratios in nutrient pools of the soil-plant system. We included nine farms, with degraded grass alone (GD), productive grass-alone (GA) and productive grass-legume pastures (GL) on each. Results showed that plant biomass production, litter deposition, soil organic P and basal soil respiration were significantly lower in GD than GA and GL. Total C, N, P and microbial P tended to be lower in soils of GD, and GD soils had less large macro-aggregates (>2000 µm) but more small macro- (250-2000 µm) and micro-aggregates (53-250 µm) than GA. Legume biomass had significantly higher N concentration and tended to have higher P concentration than grasses. This work highlights the importance of biological P cycling for sustainable pastoral systems. Analyses currently in progress will improve our understanding of the interactions of P with C and N in these systems.

W11.01 -7

C:N:P STOICHIOMETRY OF THE SOIL MICROBIAL BIOMASS IN A GRAZED GRASSLAND SITE UNDER EXPERIMENTAL P LIMITATION OR EXCESS

Griffiths Bryan^{*[1]}, Bonkowski Michael^[2], Spilles Annette^[2]

^[1]Teagasc ~ Environment Research Centre ~ Wexford ~ Ireland ^[2]University of Cologne ~ Cologne Biocenter ~ Köln ~ Germany

On a global-scale, the C:N:P ratio of soil and the soil microbial biomass tend to be constrained, with the suggestion that differences in soil microbial biomass element ratios could provide an insight into nutrient limitation in terrestrial ecosystems. Previous work on cut, rather than grazed, grassland showed clearly that both microbial biomass P and the biomass C:P were sensitive to long-term fertiliser regimes. Given the changing inputs of inorganic nutrients to many grassland soils we wanted to determine whether the stoichiometry of the soil microbial biomass could be affected by an unbalanced nutrient supply and if we could experimentally show nutrient limitation of the soil microbial biomass. We sampled plots from a long term grazing trial instigated in 1968 in which phosphorus has been applied annually at 0 (P0), 15 (P15) and 30 (P30) kg ha⁻¹, with a split in 1999 to reduce P applications to the high-P plots and increase P to the low-P plots. Increasing fertiliser P increased microbial biomass C, N and P, and the C:P ratio but did not significantly affect the biomass C:N ratio. Substrate induced respiration indicated differential nutrient limitation, with the 0 P treatment having the smallest slopes and respiratory quotient. Multi-variate analysis grouped the treatments as: [0-0]; [15-15/15-5]; [0-30/30-0]; [30-30]. Analysis of the nematode and microbial community structure revealed a shift in the bacterial: fungal ratio which might explain the observed differences in microbial biomass C:N:P.

TRANSITION METAL STABLE ISOTOPE SYSTEMS IN SOIL SCIENCE

Bigalke Moritz^{*[1]}, Wilcke Wolfgang^[1]

^[1]Geographic Institute University of Bern ~ Soil Science Group ~ Bern ~ Switzerland

Further to the established use of traditional stable isotope systems like those of H, C, N, O or S, application of a new group of non-traditional “heavy” stable isotope systems starts to develop. Although some non-traditional isotope systems have been investigated by thermal ionization mass spectrometry (TIMS) since the 1950s, the development of multicollector inductively-coupled mass spectrometry (MC-ICP-MS) about 20 years ago rendered new isotope systems accessible and shortened analysis time. In Soil Science, transition metal isotope systems have been successfully used to investigate into the fate and sources of metals in soils. Because of small but analytically accessible fractionations, the analysis of stable metal isotopes gives important information about the fate of metals during differentiation of soils, transport processes in soil and uptake of metals by organisms. A particularly promising field is elucidating the behavior of redox-sensitive metals in water-influenced soils and sediments because of pronounced isotope fractionation during redox reactions. Moreover, different isotope compositions of pollution sources and soils and the strong isotope fractionation of elements with low boiling points during metal production enable identification of metal pollution sources. Stable isotopes offer new insights into the behavior of transition metals in soils and sediments, which are inaccessible with other analytical methods. They integrate information over long time scales and are therefore especially useful to elucidate long-term processes. In the proposed presentation I will give an overview about analytical techniques and applications of stable transition metal isotopes in Soil Science, focusing on strength and weaknesses of this approach.

^[1]EcoLab (Laboratoire d'écologie fonctionnelle) ~ 31326 ~ Castanet-Tolosan ~ France ^[2]INRA ~ 84914 ~ Avignon ~ France ^[3]ADEME ~ 49004 ~ Angers ~ France

? Metal-enriched atmospheric fine and ultra-fine particulate matters (PM) are currently rejected in environment increasing significantly ecosystem pollution by metals. Few data are currently available concerning metals impact on environment and human health. In the context of Reach reglementation, the study of pollutant fate and impact on the biosphere is required, as well as the developpement of new tools for sanitary risk assessment. Earthworm is a key organism to assess soil quality. By its bioturbation activities, earthworm could modify metal bioaccessibility and bioavailability in soils (in relation with their compartimentations and their speciations). In this context, several experiments are performed to: - Estimate the difference of metals bioaccessibility between polluted soils influence by bioturbation or not. - Determine earthworm influence on metal speciation by studying ingested soils and casts. - Asses ecotoxicology impact of metal from atmospheric PM on earthworms. ? Different polluted soils (historically polluted and spiked soils), PM and two species of earthworms : *L. terrestris* (ecologically relevant) and *E. fetida* (international standard for ecotoxicology tests) will be used for experiments in laboratory or in field. For the different soils before and after bioturbation : i) the metal bioaccessibility will be determined in vitro by the UBM test; ii) metal phytoavailability will be assessed by the study of plant uptake; iii) microscopic (MEB-EDS) and spectrometric (Raman, XRF et Exafs) techniques will be used to determine potential changes in metal speciation (cast study); iv) general parameter like survival, biomasse changes, cast production and burrowing activities will be studied to assess the ecotoxicity of metals.

S12.01 -3

TRACE METAL CONTENTS IN AGRICULTURAL TOPSOILS AND SUBSOILS OF THE ISLAND OF RAB, CROATIA

Bakic Helena^[1], Romic Marija^[1], Jokovic Lucija^[2]

^[1]Faculty of Agriculture ~ Department of Soil Amelioration ~ Zagreb ~ Croatia ^[2]Vrelo d.o.o. ~ Water - Collection, purification, distribution, appliances ~ Rab ~ Croatia

The Island of Rab, located in the northern part of the Adriatic Sea, is part of the Kvarner island group. The complex pedological structure of the island is caused by a great variability of its karst underground. In relation to this, geochemical characteristics and soil types largely determine the yield quality. Owing to intensive agricultural production in such environments, due to geological and climatic conditions and anthropogenic influence, trace metals can readily be transferred to soil solution, and leached to groundwater, vegetation and ultimately humans. Other sources of trace metals, including natural weathering processes, can also contribute to the presence of trace metals in soil. This can pose a threat to water sources, which are located in the central flysch zone, a large potential water source for agriculture and drinking water. To assess the current situation of soils a multi-element geochemical survey was conducted. Following a 500 m and 1 km square grid, 42 topsoil and 31 subsoil samples were collected. Soil properties and 16 soil element contents were determined in order to (i) characterize agricultural soils, (ii) analyze the relationship between trace metal contents and soil properties, and (iii) identify lithogenic and anthropogenic sources contributing to trace metal content in soils, by using univariate and multivariate statistics, and by producing interpolation maps. The trace metal contents do not exceed the threshold values established by Croatian government regulation, with the exception of copper. A high chromium, nickel and cadmium concentration in spots seems to be of lithogenic origin.

NUTRIENT AND POLLUTANT STATUS IN ARABLE SOILS IN THE PERI-URBAN REGION OF BEIJING

Roelcke Marco^{*[1]}, Heimann Lisa^[1], Ostermann Anne^[2], Hou Yong^[3], Ma Wenqi^[3], Xue Qiaoyun^[4], Lin Xianyang^[4], Welp Gerd^[2], Amelung Wulf^[2], Nieder Rolf^[1]

^[1]Technische Universität Braunschweig ~ Institute of Geoecology ~ Braunschweig ~ Germany ^[2]University of Bonn ~ Institute of Crop Science and Resource Conservation (INRES) - Soil Science ~ Bonn ~ Germany ^[3]Agricultural University of Hebei (AUH) ~ College of Resources and Environmental Science ~ Baoding ~ China ^[4]Zhejiang University ~ College of Environmental and Resource Sciences ~ Hangzhou ~ China

China's land-use and agricultural production are undergoing rapid changes, especially in the peri-urban areas. In the Shunyi District of Beijing multiple cropping systems are accompanied by an industrialized animal production with very high livestock densities of 15 livestock units ha⁻¹, as well as high nitrogen (N) deposition rates. For the determination of the soil nutrient and pollutant status, a joint Chinese and German soil screening covering 2 soil types (Eutric Cambisols, Luvic Cambisols) and 5 typical double or multiple cropping systems (winter wheat-summer maize, spring maize-Chinese cabbage, vegetables, orchards, poplar plantations) was carried out in Shunyi from 2009 to 2011. Soils were sampled on 26 selected plots in 0-200 cm in 6 depth increments, and analyzed for total and mineral (or plant available) macronutrients (N, P, K, S) contents, soil organic matter, DOC and DON, as well as heavy metals and antibiotics. Results over three years (six consecutive cropping seasons) showed a very high accumulation of mineral N, available P and K in soil. These nutrient contents far exceeding crop-specific demand are prone to leaching and to gaseous losses to the environment. For several of the heavy metals analyzed (Cu, Zn, Cd), the "natural background value" (Chinese standards) and in some cases also the "precaution value" (German Directive) were exceeded. A screening for several substances of the antibiotic classes of Sulfonamides and Tetracyclines detected a widespread top-soil contamination. Recommendations for a reduction of the current nutrient and pollutant loads, taking into account environmental, economical and farmers' behavioral aspects will be given.

S12.01 -5

SOIL POLLUTION MEASUREMENTS IN THE QUIRRA AREA, SARDINIA ISLAND (ITALY)

Zucchetti Massimo*^[1]

^[1] Politecnico di Torino ~ DENER ~ Torino ~ Italy

Quirra is a village located in the Italian Sardinia Island, close to a big military polygon, PISQ = "Poligono sperimentale di addestramento interforze del Salto Quirra" ("Salto di Quirra Polygon" and firing range), where ballistic missiles and weapons are tested. The PISQ is used – since at least fifty years – for missiles and weapons testing. Many environmental pollutants have supposedly been released due to PISQ activities. Being a well-known air force rocket range, where new rocket propulsion systems – for both military and civil use – are tested, airborne release of toxic and teratogenic chemical substances is a quite probable effect of these tests. Also, test explosions of bombs and weapons may have had similar results, with environmental contamination with dioxins, heavy metals and other toxic chemicals. Recent environmental assessments and measurements have been performed in the PISQ area, after the Italian justice has asked to determine the origin of the Quirra syndrome. In particular: - Measurement of radioactive pollution in environmental matrices, like soil, mushrooms, lichens, seaweeds, and many others - Assessment of the presence of heavy metals and other chemical pollutants in soil and other selected matrices around PISQ The paper shows the results of those recent measurements and draws some conclusions on the causes of environmental pollution in the Quirra area.

^[1]Hebrew University ~ Soil and Water Sci. ~ Rehovot ~ Israel

In this study we investigated the behavior (transport, sorption-desorption and plant uptake) of pharmaceutical compounds (PCs) in agricultural soils. All the studied PCs were detected in reclaimed wastewater used for crop irrigation. The PCs, carbamazepine and diclofenac were significantly retarded in soil samples rich with soil organic matter (SOM) and/or amended with composted biosolids. Our data suggest that most of the studied PCs can be classified as slow-mobile compounds in SOM-rich soil layers; however when these compounds pass this layer and/or introduced into SOM-poor soils, their mobility increases significantly. In regards to the chemistry of the solution, it is concluded that the main factor affecting the mobility of PCs is the pH of the solution and not the DOM concentration. A greenhouse experiment using fresh water and reclaimed wastewater spiked, or not, with persistent PC, carbamazepine, at typical concentration in effluents revealed that it can be taken up and bioaccumulated from its indigenous concentration in reclaimed wastewater. The bioaccumulation factor for the fruits was significantly lower than the value calculated for the leaves. Our experimental data suggest that uptake of carbamazepine can be considered passive uptake governed by water mass flow. This study emphasizes the potential uptake of active pharmaceutical compounds by crops in organic-matter-poor soils irrigated with reclaimed wastewater and highlights the potential risks associated with this agricultural practice.

ADSORPTION OF WEAK ORGANIC ACID ANIONS TO BLACK CARBON: PROTON EXCHANGE-ENABLED ADSORPTION AND ELEVATION OF THE PKA ON THE SURFACE

Pignatello Joseph^{*[1]}, Ni Jinzhi^[2], Teixido Marc^[3]

^[1]Connecticut Agricultural Experiment Station ~ Environmental Sciences ~ New Haven, Connecticut ~ United States

^[2]Fujian Normal University ~ College of Geographical Sciences, ~ Fuzhou ~ China ^[3]University of Barcelona ~ Departament de Química Analítica ~ Barcelona ~ Spain

Adsorption of ionogenic organic compounds to black carbon is poorly understood. We examined adsorption of two aromatic carboxylic acid allelochemicals, cinnamic and coumaric (pKa 4.4), and a sulfonamide antibiotic, sulfamethazine (pKa of sulfonamide group, 7.2) to a wood charcoal (biochar, Eucalyptus, 600 °C). Starting at a pH where acid dissociation in solution is complete, adsorption led to release of hydroxide due to proton exchange ($A^- + H_2O = AH + OH^-$). After correction for biochar buffering, hydroxide release was stoichiometric at $pH = pK_a + 3$ (carboxylic acids) or $pH = pK_a + 2$ (sulfamethazine), becoming less so as the pH rose with continued loading. The proton exchange step is thermodynamically unfavorable ($\Delta G^0 = +55$ kJ/mol for the carboxylates and +42 kJ/mol for sulfonamidate) and not fully compensated by the increase in hydrophobicity (-10 to -17 kJ/mole). Adsorption is thus enabled by formation of a charge-assisted H-bond, (-)CAHB, between AH and a surface carboxylate or phenolate group, depicted as (A...H...O-surf)-. Classified as a 'low-barrier' H-bond, the (-)CAHB between groups having similar pKa values is exceptionally strong because the proton is shared nearly equally, giving the bond high covalent character. The (-)CAHB contributes about -50 to -56 kJ/mol to adsorption free energy which, together with the hydrophobic effect, overcomes the proton exchange penalty. The proton exchange/(-)CAHB pathway, in effect, increases the pKa of the acid on the surface relative to bulk solution. It appears applicable to other weak acids, including humic substances, on carbonaceous materials.

S12.02 -3

PLANT AND SOIL BACTERIA RESPONSE TO SULFADIAZINE EXPOSURE

Michelini Lucia^{*[1]}, Reichel Rüdiger^[2], Ghisi Rossella^[1], Thiele-bruhn Sören^[2]

^[1]University of Padova ~ Department of Agricultural Biotechnology ~ Padova ~ Italy ^[2]University of Trier ~ Department of Soil Science ~ Trier ~ Germany

Agricultural soils are often contaminated with pharmaceutical antibiotics, used for the treatment of livestock. Existing publications show the persistence and effectiveness of pharmaceutical antibiotics in soil. Consequently antibiotics might be transferred to food plants, thus entering the human food chain. However, reports on the uptake in and effects on plants are rather scarce. In the study presented, uptake of the sulfonamide sulfadiazine (SDZ) by *Salix fragilis* L. and *Zea maize* L. plants grown for 40 days in soil with 10 and 200 mg kg⁻¹ SDZ was investigated. Plant uptake was determined by accelerated solvent extraction and LC-MS/MS detection in roots, leaves, rhizosphere and bulk soil samples. Phytotoxic effects were recorded during the experimental period through biometric measurements. Furthermore, SDZ effects on the rhizosphere microbial community structure was analyzed. Bioconcentration factors revealed higher accumulation potential for *Salix fragilis* L. than *Zea maize* L. plants, which might be used for phytoremediation purposes. Also, SDZ was transferred from roots to stems and leaves, while the formation of SDZ metabolites was subordinate. While 200 mg SDZ kg⁻¹ caused serious damages in the stem and leaf development of willows and the death of several maize plants. On the contrary, both plant species widely tolerated SDZ at concentrations up to 10 mg kg⁻¹, although some minor effects and especially alterations of the root morphology were evident. The latter was paralleled by strong influences even of the lower antibiotic dose on the microbial community structure in the rhizosphere, identified by PCR- DGGE of 16S rDNA profiles.

S12.02 -4

UPTAKE AND TRANSFORMATION OF EMERGING POLLUTANTS IN SOIL BY PLANTS USED FOR FOOD AND FEED PRODUCTION

Reemtsma Thorsten^{*[1]}, Macherius Andre^[1], Moeder Monika^[1]

^[1]Helmholtz Centre for Environmental Research ~ Department of Analytical Chemistry ~ Leipzig ~ Germany

*Sewage sludge is frequently applied to agricultural land as fertilizer and with it poorly degradable moderately polar and non-polar organic contaminants are transferred to the soil/water/plant system. Depending on the physico-chemical properties and the biological stability a part of these contaminants may be taken up by agricultural plants growing on sludge amended soil and may, thus, enter the food chain. Within plants, such contaminants may be distributed, deposited and transformed into metabolites of unknown properties. Besides the processes in soil also those in plants may determine a contaminants fate and the risk associated with the practice of fertilization with sewage sludge. We have investigated the uptake of selected organic compounds by a variety of agricultural plants growing in spiked soil: polycyclic musk compounds, the UV filter octocrylene, the antibacterial agent triclosan and the plastic additive N-butyl benzolsulfonamide. To investigate uptake and translocation of the considered substances, the mature plants were separated into root peel, root core, and analysed separately using a modified QuEChERS procedure and GC-MS analysis. The results indicated an inverse correlation between the bioconcentration factors and the soils' organic matter content. The translocation of the xenobiotics from root peel into root core and the aerial parts of the plants was confirmed. Additionally, triclosan exposure studies with *Daucus carota* cell suspensions indicate that triclosan is conjugated rather than degraded in the plants. Uptake by and transformation in plants may require further consideration and closer investigation for an adequate risk assessment of sludge disposal on agricultural land.*

S12.02 -5

SORPTION AND ACCUMULATION OF HUMAN PHARMACEUTICALS IN WASTEWATER IRRIGATED FIELDS IN THE MEZQUITAL VALLEY, MEXICO

Dalkmann Philipp^[4], Willaschek Elisha^[4], Siebe Christina^[2], Amelung Wulf^[4], Siemens Jan^[4]

^[1]University of Bonn ~ INRES - Soil Science ~ Bonn ~ Germany ^[2]National Autonomous University of Mexico ~ Institute of Geology ~ Mexico City ~ Mexico ^[3]University of Bonn ~ 1Institute of Crop Science and Resource Conservation – Division Soil Science ~ Bonn ~ Germany ^[4]University of Bonn ~ Institute of Crop Science and Resource Conservation – Division Soil Science ~ Bonn ~ Germany

Due to population growth and urbanization, arable fields are increasingly irrigated with untreated wastewater worldwide. Environmental and health risks, such as proliferation and formation of antibiotic resistances, caused by pharmaceutical residues are profoundly affected by the compounds' binding and accumulation in soils. The Mezquital Valley north of Mexico City is the largest wastewater irrigation area facing these risks worldwide. We investigated the accumulation and sorption of the antibiotics ciprofloxacin, sulfamethoxazole, trimethoprim, clarithromycin, and the anticonvulsant carbamazepine in soils with different duration of wastewater irrigation (0-100 years). In contrast to our expectation no accumulation of extractable ciprofloxacin and clarithromycin was detected. However, sulfamethoxazole and carbamazepine concentrations in the soils increased until a steady state of about 40 respectively 55 $\mu\text{g kg}^{-1}$ soil was reached after approximately 15 years of irrigation. The accumulation of organic matter in wastewater-irrigated soils did not increase sorption of sulfamethoxazole. (De)sorption experiments indicate that a saturation of the soils sorption capacity at least partly explains reduced sorption in irrigated soils (Freundlich KF: 0.83-1.15 $\text{mg}^{(1-N)} \text{L}^{(N)} \text{kg}^{-1}$; N: 0.68-0.75) compared to non-irrigated soil (KF: $1.85 \pm 0.09 \text{ mg}^{(1-N)} \text{L}^{(N)} \text{kg}^{-1}$, N: 0.69 ± 0.03). Sorption of ciprofloxacin was always strong irrespective the soil organic matter content and the duration of wastewater irrigation (KF: 15.72-22.25 $\text{mg}^{(1-N)} \text{L}^{(N)} \text{kg}^{-1}$, N 0.67-0.76). Strong sorption counteracts an accumulation of extractable ciprofloxacin in soil. Intermediate sorption leads to an accumulation of sulfamethoxazole and carbamezepine in soil until an equilibrium between input with wastewater and dissipation is reached. Historical records of inputs allow an estimation of dissipation rates.

S12.02 -6

OCCURRENCE AND SORPTION OF FLUOROQUINOLONE ANTIBIOTICS IN BRAZILIAN SOILS

Leal Rafael Marques Pereira^[1], Figueira Rafael Fernandes^[1], Tornisielo Valdemar Luiz^[1], Regitano Jussara Borges^{*[3]}

^[1]USP ~ Ecotoxicology ~ Piracicaba ~ Brazil ^[2]USP - ESALQ ~ Soil Science ~ Piracicaba ~ Brazil ^[3]USP ~ Soil Science ~ Piracicaba ~ Brazil

The occurrence, behavior and potential negative impacts of antibiotics in Brazilian soils are still largely ignored. This work evaluated the occurrence of four fluoroquinolone compounds (norfloxacin, ciprofloxacin, danofloxacin and enrofloxacin) in eleven soils regularly fertilized with poultry litter, as well as their sorption behavior in other twelve soils with contrasting physical, chemical and mineralogical properties. The compounds were analyzed by HPLC, using fluorescence detector, and sorption was evaluated in a single concentration (90 mg kg⁻¹), following OECD guidelines. Enrofloxacin was the only fluoroquinolone detected (27% of the soils, average concentration of 18.7 µg kg⁻¹). This concentration is compatible with those found in previous works on European soils. Low levels may be related to a fast degradation in tropical conditions (higher temperatures) and/or with intrinsic difficulties with extraction due to their very high sorption potential. Sorption to soils was highly variable, but very high for all compounds. K_d (L kg⁻¹) ranged from 544 to 124,880 (average = 24,800) for enrofloxacin, from 848 to 127,466 (average = 25,900) for danofloxacin, from 727 to 261,147 (average = 37,100) for ciprofloxacin, and from 1000 to 156,927 (average K_d = 30,700) for norfloxacin. These sorption values were much higher than those found for temperate conditions (K_d range from 260 to 5012 L kg⁻¹), which suggest that in tropical conditions sorption of fluoroquinolones is even higher. Statistical analyses showed that cation exchange capacity and clay content were the main factors influencing sorption behavior.

TEMPORAL AND SPATIAL VARIATION OF IRON AND PHOSPHORUS STATUS IN A WETLAND SOIL

Borggaard Ole K. ^{*[1]}

^[1]University of Copenhagen ~ Basic Sciences and Environment ~ Frederiksberg ~ Denmark

Wetland soils may act as sinks for phosphorus (P) from agricultural soils and fluvial sediments. However, the sorption of P is sensitive to the redox conditions in the soil, especially to the degree of iron (Fe) reduction. When soils become flooded and anoxic, FeIII is reduced and P sorption decreases, but the relationship between Fe and P solubility under variable field conditions is not very clear. A grid of 4 x 5 sampling points at a distance of 15 m was laid out next to the Odense River, Denmark and the redox conditions were monitored from late March until early June. The degree of Fe reduction (FeII/FeIII), which includes soluble and sorbed FeII and total non-silicate Fe (FeIII); the distribution coefficient (Kd) for FeII varied between 75 and 315 L kg⁻¹. The highest average degree of Fe reduction was measured at the beginning of April (76%) and it decreased to 36% within only nine weeks. Not only the temporal, but also the spatial variability was high. The mean coefficient of variation varied between 32% and 96% in the different sampling rounds. The temporal and spatial variation of Fe and P solution concentrations was even higher. When the degree of Fe reduction was highest, P in solution was 24 µM and it decreased by a factor six under the most oxic conditions. Hence, to assess the abilities of a wetland soil to retain P, it is mandatory to have a high sampling resolution over longer periods of time.

Tamarix are salt-extruding species naturally distributed in coastal areas and salt marshes, and they are often the only woody species growing under such extreme conditions. Recently, it has been demonstrated that *Tamarix* spp. extrude cadmium from their salt glands, suggesting a potential use of these plants for phytoextraction purposes. In order to test the interaction between water salinity and heavy-metal pollution, cuttings of *Tamarix gallica* L. were planted in pots containing heavy-metal polluted soils collected in the surrounding of a former lead industry of Marseille littoral. After three months, saline solutions (0, 100, 200 and 400 mM) were used for irrigation. The impact of the treatments on leaf functionality was evaluated by measuring leaf gas exchanges, chlorophyll fluorescence and, chlorophyll, phenols, flavonoids and anthocyanins contents. Moreover, SEM observations coupled to EDXS analysis were used to determine elements (Na, Cl, and metals such as Pb, As and Al) presence and location on the leaf surface and in the leaf and root tissues. Soils and plants (aerial and root parts) were analysed by ICP-AES and GF-AAS to determine the elemental contents. Higher photosynthetic rates were measured in *Tamarix gallica* grown in heavy-metal polluted soils under 100 mM, compared to non-saline or higher saline conditions. On the other hand, heavy-metals reduced stomatal conductance, but not under moderate salinity (100 mM). The presence of Al on the root surface was observed in plants grown in polluted soils especially under non-saline conditions, because salinity enhanced Al extrusion through salt glands.

DYNAMIC OF HEAVY METALS AND ARSENIC IN FLOODPLAIN SOILS – RESULTS OF FIELD AND LYSIMETER EXPERIMENTS

Rupp Holger^[1], Bolze Sebastian^[1], Meissner Ralph^[1]

^[1]Helmholtz Centr for Environmental Research - UFZ ~ Soil Physics ~ Falkenberg ~ Germany

Floodplains along great rivers have to buffer considerable loads of pollutants. Tolerable concentrations of heavy metals and arsenic in soil and soil solution are here often exceeded. Therefore, approaches for management and remediation of highly contaminated floodplain areas are urgently needed. Detailed processes knowledge of heavy metal dynamics in frequently flooded soils is a basic requirement. Hence, the release and immobilization of heavy metals and arsenic in floodplain soil was studied. Investigations were carried out at lysimeter and field scale under realistic conditions. Soil monoliths (diameter 30 cm, height 70 cm) were gathered for lysimeter studies. The lysimeters and field sites were furnished with comparable measuring instrumentation. Groundwater level inside lysimeters is adjustable. The seasonal groundwater fluctuation and also periods of rapid alternating water levels was simulated. A soil-hydrological measurement facility was established in the floodplain to monitor parameters determine metals mobility (EH, temperature, soil moisture, pH) and to gather soil solution via suction cups. The studies in both scales proved a significant influence of water level, redox and pH on heavy metals and arsenic concentration in soil solution. Furthermore, the simulation of midterm flooding and drought (each 3 month, respectively) and short-term water level alteration (each 6 weeks, respectively) showed comparable patterns of metal mobilization and immobilization. It can be concluded that studies in both scales are a valuable tool to come to a comprehensive understanding of processes determining the behaviour of heavy metals in arsenic in floodplain soils.

S12.03 -4

MOBILITY OF ARSENIC IN IRRIGATED RICE SYSTEMS ON FLOODPLAIN SOILS

Mcgrath Steve*^[1], Zhao Fangjie^[1], Stroud Jacqueline^[1], Khan Asaduzzaman^[2]

^[1]Rothamsted Research ~ SGS ~ Harpenden ~ United Kingdom ^[2]Sher-e-Bangla Agricultural University ~ Soil Science ~ Dhaka ~ Bangladesh

Inorganic arsenic is a non-threshold carcinogen and rice is a major source of this to human populations who depend on rice in their diet. In the dry season, rice is cultivated by irrigation with water pumped from shallow tube wells in many lowland areas in Asia. Such water can contain large concentrations of arsenic, which is then deposited in the paddy fields. Incubations studies with a number of soils from Bangladesh, China and the UK showed that the arsenite species (AsIII), which is taken up by rice roots via the silicon uptake pathway, is mobilised under the reducing conditions in flooded soils. Bangladeshi soils, which were contaminated by As in irrigation water, had greater potential As(III) mobilisation than other soils. We also used 73As to determine the chemically labile in soils (E value) and phytoavailable pools (L value in rice). E values ranged from 6-21% of the total As. A simple phosphate extract of soils was better than soil E values for predicting the potential mobilisation of As into pore water. In four out of five soils, the L value of rice was similar to the E value, and this increased in flooded versus aerobic treatments. We interpret this as being due to the reductive dissolution of Fe oxides/hydroxides which releases sorbed As into solution and exposes more As in the solid phase for exchange. Soil management strategies for mitigation of As accumulation by rice will be discussed.

S12.03 -5

CHARACTERISATION OF THE TRANSFER AND BIODEGRADATION OF CHLOROACETAMIDE HERBICIDES IN LAB-SCALE WETLANDS

Maillard Elodie^[1], Elsayed Omnia^[1], Vuilleumier Stéphane^[2], Imfeld Gwenaël^[1]

^[1]Laboratory of Hydrology and Geochemistry of Strasbourg ~ CNRS ~ Strasbourg ~ France ^[2]Laboratory of Molecular Genetics, Genomics and Microbiology, University of Strasbourg ~ CNRS ~ Strasbourg ~ France

Chloroacetamide herbicides are extensively used in the U.S. and in Europe in a variety of crops, including maize, sugar beet or sunflower. Biodegradation is a major attenuation process of chloroacetamides in water and soil ecosystems. which can be enantioselective, and thus change the enantiomeric signatures of chiral chloroacetamides. However, knowledge on the transfer and biodegradation of chloroacetamides in wetlands in relation with biogeochemical conditions and changes in the enantiomeric signatures is scarce. Here, we examine the transfer and in situ biodegradation of metolachlor, alachlor and acetochlor in lab-scale wetlands by combining hydrochemical and biomolecular approaches with enantiomeric and compound-specific isotope analysis (CSIA). Changes in hydrochemical conditions are evaluated using redox-sensitive species. Oxygen concentrations ranged from 6.8 ± 0.8 mg L⁻¹ to 0.7 ± 1.3 mg L⁻¹, respectively, at the inlet and outlet of the wetlands. Changes in the herbicides, their enantiomeric signatures and their degradation products are quantified over the flow path and over time. CSIA methods are developed for assessing the in situ biodegradation with respect to the biogeochemical changes in the wetlands. In parallel, the structures of microbial communities in wetland pore water samples are characterized based on T-RFLP analyses of 16S rRNA genes. Based on a multiple-method approach, the results underscore the linkage between the microbial communities, changes of hydrochemical conditions and degradation of chloroacetamide herbicides in wetlands.

S12.03 -6

TERNARY COMPLEX FORMATION BETWEEN ARSENATE AND FERRIC IRON COMPLEXES OF HUMIC SUBSTANCES

Mikutta Christian*^[1], Kretzschmar Ruben^[1]

^[1]ETH Zurich ~ Environmental Sciences ~ Zurich ~ Switzerland

Formation of ternary complexes between arsenic (As) oxyanions and ferric iron (Fe) complexes of humic substances (HS) is often hypothesized to represent a major mechanism for As-HS interactions under oxic conditions. To investigate the molecular-scale interaction between arsenate, As(V), and HS in the presence of Fe(III), we reacted fulvic and humic acids with Fe(III) and equilibrated the Fe(III)-HS complexes formed with As(V) at pH 7 (molar Fe/As ~10). The local coordination environments of As and Fe were subsequently studied by means of X-ray absorption spectroscopy. Our results show that 4.5-12.5 $\mu\text{mol As(V)/g HS}$ (25-70% of total As) was associated with Fe(III). At least 70% of this As pool was bound to Fe(III)-HS complexes via inner-sphere complexation. Results obtained from shell fits of As K-edge extended X-ray absorption fine structure (EXAFS) spectra were consistent with a monodentate binuclear and monodentate mononuclear complex stabilized by H-bonds ($R_{\text{As-Fe}} = 3.30 \text{ \AA}$). The analysis of Fe K-edge EXAFS spectra revealed that Fe in Fe(III)-HS complexes was predominantly present as oligomeric Fe(III) clusters at neutral pH. Shell-fit results complied with a structural motif in which three corner-sharing $\text{Fe}(\text{O},\text{OH})_6$ octahedra linked by a single $\mu_3\text{-O}$ bridge form a planar Fe trimer. In these complexes, the average Fe-C and Fe-Fe bond distances were 2.95 \AA and 3.47 \AA , respectively. Our study provides spectroscopic evidence for ternary complex formation between As(V) and Fe(III)-HS complexes, suggesting that this binding mechanism is of fundamental importance for the cycling of oxyanions such as As(V) in oxic soils and sediments.

Widespread use of polychlorinated biphenyls (PCBs), recalcitrant and toxic compounds, yielded in the contamination of the environment. In Croatia, warfare activities in the 90s led to heavy PCBs contamination of several sites. Remediation of PCBs contaminated sites is essential to restore environmental quality. In this context, we report the principal steps that yielded in the implementation of PCB bioremediation assay. The first step was to isolate seed culture able to transform PCBs from the contaminated site in Zadar (Croatia). A mixed bacterial community (TSZ7), enriched using biphenyl as the only carbon source, showed high capacities to degrade a wide range of PCBs (56-60% degradation of the PCBs in liquid culture). Strain Z6, identified as *Rhodococcus* sp., was found as the active PCB-degrading member of the mixed community. Intermediary metabolites were identified using GC-MS analysis and single PCB congeners (2,4,4'- and 2,2',5,5'- chlorobiphenyl). The second step was to select natural compounds such as carvone, tested as inducers of PCB degrading pathway, and soya lecithin, tested to enhance PCB bioavailability. The third step was to develop and monitor a small-scale bioremediation assay. Both biostimulation and bioaugmentation (inoculation with TSZ7 or *Rhodococcus* sp. Z6) strategies were tested, leading to the reduction of significant amount of PCBs. The last step was to address the impact of bioremediation on the global indigenous microbial community and on the PCB-degrading functional community. These results gave new insights into processes following bioremediation practices and therefore could help to promote implementation of the bioremediation in restoration of PCB-contaminated sites.

*The continuous stream of sediment dredged from harbors and channels to provide shipping traffic efficiency is a considerable and ongoing problem worldwide recognized. In this study (European Project AGRIPORT) phytoremediation has been considered as a sustainable reclamation technology for bringing slightly polluted brackish sediments into productive use. The experimentation has been carried out in containers of about 1 m³ filled with contaminated (heavy metals and hydrocarbons) brackish sediments. The fine particles granulometric composition made necessary a bio-physical pre-conditioning of sediments by mixing them with an agronomic structured soil (30% v/v). Moreover, a high quality compost was mixed with the sediment-soil matrix at surface level (40t/ha) with the aim of favouring the initial adaptation of the selected vegetal species. Different plant treatments were chosen: i) *Paspalum vaginatum*, ii) *Phragmites australis*, iii) *Spartium junceum* + *Paspalum vaginatum*, iv) *Nerium oleander*+ *Paspalum vaginatum*, v) *Tamarix gallica*+ *Paspalum vaginatum*, and vi) No plants used as control. After one year from the beginning of the experimentation all the plant species were still in healthy condition and well developed. During the time, increasing values of nitrate were generally observed in the planted sediments, suggesting an improvement of the chemico-physical conditions for microorganisms and plants. The stimulation of the microbial activity in the planted sediment with respect to control has been confirmed by the increase of the dehydrogenase activity. Concerning the organic and inorganic contaminant concentrations, decreased values were detected, despite the short period passed, indicating the efficiency and success of this technology for brackish sediments reclamation.*

**ENRICHMENT OF HEXACHLOROBENZENE AND 1,3,5-TRICHLOROBENZENE
TRANSFORMING BACTERIA FROM RIVER SEDIMENTS IN VIETNAM AND GERMANY**

Tran Hoa Duan^{*[1]}, Adrian Lorenz^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Isotope Biogeochemistry ~ Leipzig ~ Germany

Hexachlorobenzene is one of the most persistent environmental pollutant and is listed as one of the 12 persistent organic pollutants in the UN Stockholm Convention. Another chlorinated organic compound which also devotes attention is 1,3,5-trichlorobenzene because this congener is persistent under aerobic and anaerobic conditions and is one major product of HCB degradation under anaerobic conditions. Here we show that hexachlorobenzene and 1,3,5-trichlorobenzene were dechlorinated by mixed cultures enriched from sediments in Vietnam and Germany. The final end-products from hexachlorobenzene were 1,3,5-trichlorobenzene, 1,2-, 1,3- and 1,4-dichlorobenzene and monochlorobenzene. In different enrichments 1,3,5-trichlorobenzene was reductively dechlorinated to 1,3-dichlorobenzene and monochlorobenzene. The pathways remained stable over seven transfers. The same dechlorination patterns were reproduced when the inoculum of a culture was exposed to oxygen until the used redox indicator (resazurin) indicated a redox potential above zero. However, the pathways changed significantly when cultures were amended with 5 mg/l vancomycin. This indicated that the bacteria in our cultures which were in charge of the reductive dechlorination of hexachlorobenzene and 1,3,5-trichlorobenzene did not belong to the Dehalococcoides spp, which are very sensitive to oxygen and resistant to vancomycin. Isolation and identification of bacteria removing singly flanked and isolated chlorine substituents is essential to further understand the biochemical reasons for the reaction specificity of different enzymes. At the same time, chlorobenzenes can be considered as a chemical model also for more complex aromatic pollutants such as dioxins or PCBs.

S12.04a -4

MULTIPLE PRE-EXPOSURE OF A SOIL MICROBIAL COMMUNITY TO ORGANIC CONTAMINANTS DOES NOT ENHANCE SOIL MICROBIAL COMMUNITY FUNCTIONAL RESPONSE

Lin Deborah Shuhui*^[1], Tibbett Mark^[2]

^[1]University of Western Australia ~ School of Earth and Environment ~ Perth ~ Australia ^[2]Cranfield University ~ National Soil Resources Institute, Department of Environmental Science and Technology ~ Cranfield ~ United Kingdom

The significant increase in the rate of microbial degradation of xenobiotics in soil following a previous pollution event has been well documented. However, the microbial community functional response by which this phenomenon occurs has yet to be understood. We aimed to determine if multiple small exposures will enable the soil microbial community to adapt functionally to utilise hydrocarbon substrates more efficiently in subsequent exposure events, and if pre-exposure of the soil microbial community to 2-methylnaphthalene will selectively enhance microbial community functional response to utilise 2-methylnaphthalene or other related polyaromatic substrates. We exposed a soil sample from a site in Exmouth, Western Australia to either a single large dose, or several small multiple pre-exposures of diesel or 2-methylnaphthalene, along with a non-polluted control. A modified Community Level Physiological Profiling (CLPP) method was used to study respiration response of the different soil treatments to a range of volatile hydrocarbon substrates. The resulting CO₂ production profiles were examined by multivariate analysis. Pre-exposure to diesel did not select for specific substrates, but returned microbial community function to control levels. Pre-exposure of the soil community to small doses of 2-methylnaphthalene did not help recover microbial activity to control levels, nor did it selectively enhance microbial community functional response to utilise 2-methylnaphthalene or other aromatic substrates. Although there has been no observable difference in microbial community functional response in our study, it will be valuable to use stable isotope probing to determine specific groups of microbes that might contribute to pollutant degradation.

Although forbidden for more than 30 years, several environments in contact with polychlorinated biphenyls (PCBs) are still contaminated and even polluted. Low-cost biological processes like bioremediation can be implemented *in situ* and allow maintaining the physicochemical and biological properties of soils to be cleaned-up. Nonetheless, such a technique must be improved and controlled accurately. Associating soil bioaugmentation by a PCB-degrading bacteria with plants used as exudates suppliers is supposed to be relevant in stabilizing the *in situ* degrading activity. Our study aims at assessing the efficiency of phytoremediation-assisted bioaugmentation on a highly PCB-polluted soil (100 mg kg⁻¹). A previous *in vitro* study consisted in a screening of several PCB-degrading bacteria - inducer couples in liquid medium spiked with the seven indicator PCBs (Secher et al., submitted). *Burkholderia xenovorans* LB400 without inducer showed the best efficiency, i.e. 97% of all PCBs were removed in three weeks against 55% for the non inoculated control (dissipation). Among other plant species (*Medicago sativa*, *Brassica napus*, *Trifolium pratense*, *Lolium perenne*), *Festuca arundinacea* was selected based on its root hair development. The performance of this plant-bacteria couple was assessed in soil pots during a 12-week incubation under controlled conditions. Bioaugmented pots (9 10¹⁰ UFC g⁻¹soil), planted pots (30 seedlings per pot) and the combination of both were compared. *B. xenovorans* was monitored by qPCR (Norini et al., submitted) and its effect on the soil microflora by assessing the total bacterial population and the structure of the bacterial community by PCR-TTGE. PCB degradation was measured by GC-MS.

**IN SITU LONG-TERM EVOLUTION OF FUNGAL ABUNDANCE AND COMMUNITY STRUCTURE
IN A POLYCYCLIC AROMATIC HYDROCARBON AND HEAVY METAL CONTAMINATED SOIL:
EFFECTS OF PLANT COVER AND THERMAL DESORPTION TREATMENT**

Thion-Caupert Cécile^{*[1]}, Aurélie Cébron^[1], Thierry Beguiristain^[1], Corinne Leyval^[1]

^[1]LIMOS Nancy University ~ Faculty of Sciences ~ Nancy ~ France

Due to human activities, large volumes of soils are multipolluted by heavy metals and organic pollutants, such as polycyclic aromatic hydrocarbons, thus representing a key concern for remediation. Fungal communities in polluted environments are poorly documented, although fungi can contribute to pollutant biodegradation. A field experiment, with a multidisciplinary approach, involving microbiological, biological, chemical, ecotoxicological and pedological aspects, was set up to monitor the long-term fate and environmental impact of the organic and metallic contaminants of an industrially polluted soil (~1800 mg PAHs/kg). This 5-year field trial comprised four treatments in four replicate lysimetric plots: bare soil, soil planted with alfalfa, soil spontaneously colonized by indigenous plants, and thermally treated soil (~150 mg PAHs/kg) planted with alfalfa. Twice a year (in spring and autumn), the fungal abundance and the structure and the diversity of the fungal community were evaluated by real-time PCR and Temporal Temperature Gradient Electrophoresis (TTGE), respectively, targeting 18S rRNA genes. Our results show that the vegetal cover increased the fungal abundance and was the main driver for community structuring. The positive effect of plants on fungal density and diversity could represent a significant advantage in natural attenuation processes that rely on microbial biomass and activities. Nevertheless, the high level of pollution allowed only a small number of species, mostly Ascomycetes, to be maintained after five years. This study offered the interesting opportunity to monitor and model the structuring of the fungal community in a polluted soil and the re-colonization of a thermal desorption treated soil.

Due to the large number of contaminated field sites in Europe, monitored natural attenuation frequently is the only financially feasible site remediation option. One of the few methods providing evidence of natural attenuation, which are accepted by authorities, is the recently developed in situ microcosm approach (BACTRAP®). Until now, the in situ microcosms were only applicable in aquifers equipped with groundwater wells. To overcome these limitations, a new Direct-Push BACTRAP-probe was developed on basis of the Geoprobe® infrastructure. This allows extending the approach to field sites without monitoring wells and measuring microbial activity in the vadose zone above the aquifer. Both Classical and Direct-Push BACTRAPs were incubated in the centre and at the fringe of the BTEX plume at the ModelPROBE reference site Zeitz (Germany). During microbial degradation of the ¹³C labelled substrate, the ¹³C label was incorporated into bacterial biomass, which was determined by phospholipid fatty acid (PLFA) analysis, and provided the evidence for in situ natural attenuation. In addition, the bacterial communities on classical and Direct-Push microcosms and soil were compared by analysing PLFA patterns. Based on this it could be demonstrated that DP-BACTRAPs showed a higher abundance and enrichment of microbial signature fatty acids compared to conventional BACTRAPs. Also the microbial community on DP-BACTRAPs was more related to soil microbial community. Concluding, Direct-Push based BACTRAPs offer a promising and cost efficient way for monitoring natural attenuation or remediation success at field sites currently inaccessible by the BACTRAP technique.

Pseudomans spp. UC7153 is a strain recently isolated from the Madaccio ice glacier in the Italian alps. Chemical and microbiological analyses have shown the ability of this strain to degrade phenanthrene and other xenobiotics, with good efficiencies at temperature low to 4 °C. Given the potential interest of applying degrading strains for the bioremediation of cold environments, a full genomic sequencing of the strain was then carried out. Genomic DNA was extracted fragmented, and sequenced with an Illumina Hiseq 1000 at 100 bp in paired end mode. 80 millions of fragments in paired ends were produced and filtered to remove low quality sequences, adapters and duplicated sequences. 123 contigs were assembled, covering a total genomic size of 67 Mbp. A first functional annotation of *Pseudomans* spp. UC7153 identified 6221 genes, which have been screened for functional genes of environmental interest, such as genes for xenobiotics degradation and adaptation to cold conditions. Several oxygenases have been identified, as well as dehalogenases potentially involved in the degradation of chlorinated compounds and genes coding for trace elements resistance. Genomic information is being further analysed and coupled to biodegradation experiments in order to improve the understanding of the environmental behaviour of this promising xenobiotic degrading bacterium.

The answer to the title question cannot be that affirmative. In bioremediation processes enzymes may play important and different roles at least in three cases: -as main responsible (either isolated or cell-bound molecules) of the transformation and/or degradation of compounds polluting the environment. The possibility of a pollutant to enter in complex metabolic pathways is very often due to the presence of a specific enzyme that performs the first, peculiar, chemical reaction, essential to render the pollutant susceptible of subsequent enzymatic transformations. -as reliable and sensitive tools to detect and measure the amount and concentration of the pollutant and/or its transformation products during the process. Several analytical assays very often utilize specific enzymatic reactions capable to detect and transform even minimal amounts of compounds -as reliable, easy and sensitive indicators of the quality and health status of the environment subjected to the bioremediation process. Enzymatic activities are easy to measure and rapidly respond to changes in soil caused by natural or anthropogenic factors and The present paper will briefly examine general concepts about the statements previously reported. Examples supporting and confirming the positive response to the title question will be illustrated.

Assessment of contaminated sites up to now is based on variable protection goals, whereby total contents and in part mobile contents are considered. Due to interactions of pollutants in soil and bound residues total contents do not reflect the actual true risk. In contrast an investigation based on availability/bioavailability of contaminants would enable a harmonization of the protection-goal-based evaluation and a closer-to-reality risk assessment for the individual location. The final direction of the joint research project BioRefine was to create assessment methods and scales for contaminants in soil based on bioavailability and to show possibilities of coast optimization. For the determination of bioavailable parts of contamination chemical analyses as well as toxicological and ecotoxicological methods were tested also considering a comparison between conventional methods according to German soil protection legislation and integration of bioavailability. While aged PAH proved to have only a low potential biological component, MHC demonstrated high resorption availability and toxic impact on soil organisms. These different results emphasize the necessity of the implementation of bioavailability in the risk assessment of contaminated sites helping to give a more real prognosis of danger. Most of the examined contaminated soils proved to have a far lower hazard potential than total contents suggest. This way extensive soil remediation procedures proved to be no more essential but diverse utilization tends to be possible. A guideline for local authorities, advisor and planning agencies was generated to facilitate decision processes for contaminated soils taking bioavailability of organic contaminants into account.

HIGHWAYS VERSUS PIPELINES – CONTRIBUTIONS OF TWO FUNGAL TRANSPORT MECHANISMS TO EFFICIENT BIOREMEDIATION

Banitz Thomas^[1], Karin Johst^[1], Lukas Y. Wick^[2], Karin Frank^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Ecological Modelling ~ Leipzig ~ Germany ^[2]Helmholtz Centre for Environmental Research - UFZ ~ Environmental Microbiology ~ Leipzig ~ Germany

Based on experimental studies, two fungus-mediated transport mechanisms have been suggested to facilitate the bacterial degradation of organic soil contaminants: bacteria may use liquid films around fungal hyphae for quick dispersal ('fungal highways'), and fungi may take up and translocate contaminants through their mycelial network ('fungal pipelines'). Both mechanisms promise to enhance the bioavailability of pollutants to degrading bacteria. However, a comparative study of their respective efficiency in increasing biodegradation performance, and its dependence on environmental conditions, has hitherto not been conducted. Taking advantage of a microbial model, we therefore investigate bacterial degradation performance in response to networks that either act as bacterial dispersal vectors ('highways') or as contaminant translocation vectors ('pipelines') or as a combination of both. We analyse biodegradation improvements compared to the situation without networks, and systematically test a variety of spatially homogeneous and heterogeneous environmental scenarios. Our results suggest that each mechanism can improve biodegradation performance. The degree of improvement, however, may vary distinctly depending on the environmental conditions, and may also be negligible under certain conditions, particularly for networks acting as 'pipelines' only. In many cases, highest biodegradation improvements emerge from the combination of both mechanisms. We therefore conclude that 'fungal highways' as well as 'fungal pipelines' should be considered for developing novel bioremediation strategies based on fungus-mediated transport. Further experimental studies should focus on detection and appropriate stimulation of the two mechanisms in typical bacteria-fungi associations in contaminated soils.

BRINGING (BIO)ACCESSIBILITY EXTRACTIONS TO THE NEXT LEVEL - COMBINING MOBILISATION MEDIUM AND INFINITE ABSORPTION SINK

Gouliarmou Varvara^{*[1]}, Mayer Philipp^[1], Collins Chris^[2], Loibner Andres P.^[3], Vasilieva Victoriya^[3]

^[1]Aarhus University ~ Department of environmental science ~ Roskilde ~ Denmark ^[2]Reading University ~ Soil Research center ~ Reading ~ United Kingdom ^[3]IFA Tulln ~ Agrobiotechnology ~ Tulln ~ Austria

Soil bioaccessibility extraction techniques are generally simple dissolution experiments, where the transferred compound to the medium are measured and considered to be bioaccessible. However, such techniques can lead to an underestimation of bioaccessibility, since they do not account for the consumption of contaminants by either degradation or absorption. It is therefore crucial to develop practical bioaccessibility extraction approaches that combine both mobilisation and consumption processes. The mobilisation medium can be chosen to either maximize desorption without attacking the matrix or even to simulate the relevant organism conditions. A sorbent can act as an infinite diffusion sink for continuously removing the mobilized contaminants from the medium. Initially, we combined cyclodextrin extraction with a polymer of poly(dimethylsiloxane) and activated carbon which lead to the contaminant trap method. This contaminant trap is a practical and simple approach for the isolation and quantification of the desorption resistant contaminants in soils, its main limitation being that it is not possible to back extract from the polymer. The next step was to find a polymer material and format that can act as infinite sink and allow simple back extraction. Silicone rods were chosen, which are already used in silicone rod extraction and passive sampling. This resulted in a better and more relevant bioaccessibility extraction approach and simplified the analytical procedures. The silicone rods were applied to both cyclodextrin solutions and artificial digestive fluids, using PAHs as model compounds. Validation experiments with spiked cyclodextrin and digestive fluids confirmed an efficient trapping of PAHs by the silicone rod.

EFFECT OF STRONG SORPTION ON BIODEGRADATION AND VOLATILIZATION OF PCBS

Ghosh Upal^[1], Paul Piuly^[1]

^[1]University of Maryland Baltimore County ~ Chemical, Biochemical, and Environmental Engineering ~ Baltimore ~ United States

Abstract One of the challenges in implementing biodegradation of semivolatile organic compounds like PCBs in the open soil/sediment environment is the need for reducing losses from volatilization or leaching during the long times required for biodegradation for these slowly degrading compounds. Our recent work has demonstrated that strong sorbent amendments like activated carbon can greatly reduce the bioavailability of PCBs in soil and sediment environments and reduce volatilization and leaching. While reduction in the availability of PCBs is beneficial for human and ecosystem exposure, the effect of bioavailability reduction on aerobic and anaerobic biodegradation is unknown. The present study evaluated loss of PCBs from field collected sediments through aerobic biotransformation and volatilization with and without activated carbon amendment. In the sediment without activated carbon amendment, incubation for 1 year in aerobic environment resulted in the mass of di, tri, and tetrachlorobiphenyls in the system to decrease by 79, 58, and 13 % respectively compared to day 0. For the activated carbon treated mesocosms the total mass of di, tri, and tetrachlorobiphenyls decreased by 60, 65, and 42 % respectively compared to day 0. The present study showed that addition of activated carbon as an amendment for stabilization of PCB contaminated sediment can greatly reduce volatilization loss of the lower chlorinated PCB homologs. Activated carbon addition also lowers bioavailability of PCBs for aerobic microbial transformation, however, our results indicate that slow aerobic biodegradation of lower chlorinated PCBs continue in the presence of activated carbon in sediments.

In situ bioremediation, either stimulated or natural attenuation, is generally considered a cost effective, minimally invasive treatment with little damage to soil function. However, even under ideal environmental conditions, bioavailability of the compound can significantly impede remediation efficiency in terms of treatment time and absolute residual concentrations. This research examines the dynamic interplay between soil matrix type, contaminant concentration, and bioavailability of a complex diesel contamination in order to identify when complete biodegradation can be achieved. To this end, biodegradation is stimulated in laboratory experiments with field collected diesel contaminated samples from different soil types (anthropogenic fill, peat, clay, and sand) and with varying degrees of contamination (high, low, or clean). Experiments last for 100 days; nutrients and oxygen are supplied and temperature is maintained at 30 °C. Absolute total petroleum hydrocarbons (TPH) concentrations as well as the bioavailable fraction are measured prior to and following biological treatment in all contaminated samples. Oxygen consumption and carbon dioxide production are measured in all batches. Results indicate that significant TPH biodegradation is possible in all contaminated samples, with removal efficiencies reaching 100% for TPH concentrations below 3 g/kg. Notably higher respiration rates in contaminated samples, as compared to clean samples, indicate the importance of full oxic conditions as a requirement for successful field treatments. In some cases, residual TPH concentrations may be above intervention values, while the remaining pool of TPH is not bioavailable and composed of higher carbon number components (>C₂₄). This indicates that bioavailability may inhibit further degradation.

It is unclear to what extent inorganic colloids bearing phosphorus (P) are detected by analytical methods. We prepared two types of colloidal P solutions using dispersed Al₂O₃ nanoparticles (< 50 nm) and ferrihydrite stabilized by natural organic matter. The dissolved P was detected by ICP-OES and the P in solution was analysed by a colorimetric method (CM; acid condition), ion chromatography (IC; alkaline eluent) and the diffusive layer in thin films technique (DGT) that has ferrihydrite as the P binding layer. The P concentrations detected by the CM method did not differ significantly from those obtained with ICP. However, the P concentrations measured by either IC or DGT decreased as the molar ratio metal/P in the colloids increased. At Al/P = 4.8, the IC and DGT measured P decreased to respectively 91% and 84% of total dissolved P and at Fe/P = 15.9 to respectively 49% and 56%. We attribute the low recovery of colloidal P in the IC method to the high pH in the IC column. We infer that colloidal P is not able to diffuse through the diffusive layer of the DGT since we could not find any Al adsorbed on the DGT eluates and since the DGT data were similar to the IC data for the ferrihydrite-Pi solution.

^[1]Wageningen University ~ Department of Soil Quality ~ Wageningen ~ Netherlands ^[2]Alterra ~ Soil Science Centre ~ Wageningen ~ Netherlands

The speciation of phosphorus (P) was investigated in pipe drain and trench water samples leached from a heavy clay soil under grassland of a dairy farm in The Netherlands. Water samples were collected at three times: (t1) in early spring, when P sources were absent for almost seven months, (t2) when rainfall followed the application of the solid cattle slurry fraction, and (t3) when rainfall followed within one day after dairy slurry application. Concentrations of Dissolved Reactive P (DRP), Dissolved Unreactive P (DUP), and Particulate P (PP) were determined. In addition, Asymmetric Flow Field-Flow-Fractionation (AF4) coupled to ICP-MS and UV-DAD was used to analyse the DUP speciation. Total P (TP) concentrations were highest at t3. At t1, TP concentrations were lowest, and dominated by DUP and PP. At t2 and t3, DRP concentrations strongly increased, and contributed >50% of the TP concentration. At t1 and t2, DUP was dominated by P associated to clay minerals (25-130 nm), with a small contribution of ternary complexes consisting of ortho-P bridged to dissolved organic matter by Al or Fe (1-5 nm). At t3, the presence of organic P nanoparticles was detected (10-50 nm). Based on their specific UV-spectrum, they are likely to be phospholipids, a major and highly soluble component of dairy manure. Since phospholipids can form vesicles >0.45 µm in size, they may explain the elevated PP concentrations measured at t3. In conclusion, the DUP speciation can vary in time and AF4 can be used to unravel the nature of DUP.

S12.05 -3

PHOSPHORUS MOBILITY AFFECTED BY SLURRY APPLICATION TECHNIQUE

Glæsner Nadia^{*[1]}, Kjaergaard Charlotte^[2], Rubæk Gitte H.^[2], Gerke Horst H.^[3], Magid Jakob^[1]

^[1]University of Copenhagen ~ Agriculture and Ecology ~ Frederiksberg ~ Denmark ^[2]University of Aarhus ~ Agroecology and Environment ~ Tjele ~ Denmark ^[3]Leibniz-Centre for Agricultural Landscape Research (ZALF) ~ Institute for Soil Landscape Research ~ Müncheberg ~ Germany

Eutrophication of fresh waters is mainly caused by phosphorus (P) losses from agricultural fields, and leaching through soil to tile drains is considered an important contributor to P losses. With growing emphasis on improving land application of manures to minimize P losses, it is critical to determine how application methods such as manure injection affect P leaching. We investigated the effect of injection and surface application of dairy slurry on mobilization and leaching of P in relation to soil texture. The studies were performed on intact soil columns (20 cm diam., 20 cm high) from the plow layer of a loam, sandy loam, and loamy sand with low to intermediate soil P content. The experimental setup was designed to study dissolved and particulate P leaching during unsaturated conditions with suction applied at the lower boundary. As transport occurs predominantly through larger pores, placing slurry away from large pores by injection decreased leaching of all P forms compared with surface application in the loam and sandy loam. Transport occurred through a larger fraction of the loamy sand allowing additional larger contact between the slurry and the soil matrix. Irrigation interruptions were introduced and induced fluctuations in leaching of nonreactive tracers, particulate P, and particles. We hypothesized that mass exchange between mobile and less mobile pore regions changed during interruptions. Leaching of dissolved inorganic and organic P was scarcely affected by irrigation regime because of high adsorption to soil surfaces. The results will be modeled using a mobile-immobile and dual-permeability modeling approach.

S12.05 -4

TRANSPORT OF DISSOLVED ORGANIC PHOSPHORUS (DOP) FROM SOIL TO SURFACE WATER ON HEAVILY MANURED GRASSLAND ON A SANDY SOIL

Verheyen Dries*^[1], Jan Diels^[1], Gerard Govers^[1], Roel Merckx^[1]

^[1]K.U.Leuven ~ Department of Earth and Environmental Sciences ~ Leuven ~ Belgium

Accumulation of soil P because of animal manure spreading from intensive livestock production is a serious threat to water quality in the agricultural regions in Flanders. The organic P in the soil solution accounts for the main fraction of P in the soil water. Certainly in sandy soils with low P sorption capacities and a shallow groundwater table, the subsurface transport of dissolved organic phosphorus (DOP) can be of great significance. The quantitative importance and potential mobility of DOP is known. But, despite the importance, its precise role in transfer to surface waters remains poorly understood. To investigate the DOP fluxes, a heavy manured grassland in the Campine region in Flanders is equipped with piezometers and suction cups. The field has a degree of phosphorus saturation of 45%. The field is drained by ditches that flow in a river next to the field. Concentrations of different forms of dissolved P (orthophosphate, colloidal and organic) were monitored each week in the groundwater, soil water and drainage ditches. Also, the water levels of the drainage ditches, the river and the groundwater were recorded with water level loggers. Together with the determination and modeling of the groundwater flow, a quantification on field scale was assessed of the different fluxes of phosphorus from the soil to the surface water. This research indicates that measures of phosphorus control should be specified on fields with unreactive soils and a high connectivity to surface water.

EFFECT OF DIFFERENT SLURRY APPLICATION TECHNIQUES ON PHOSPHORUS OUTPUT INTO TILE DRAINS

Hösl Rosemarie^{*[1]}, Strauss Peter^[1], Ulrich Hanna^[2]

^[1]Federal Agency for Water Management ~ Institute for Land and Water Management Research ~ Petzenkirchen ~ Austria ^[2]Water Management Agency ~ Traunstein ~ Traunstein ~ Germany

In Austria and Bavaria, slurry application employing near ground application techniques is subsidized to promote positive effects on gaseous N losses. We hypothesized; that additional effects regarding P transport might occur whenever near ground application is done on tile drained soils. Therefore we carried out a rainfall simulation study to evaluate the effect of near ground application techniques on P losses into tile drains. Slurry was applied on drained pasture plots near lake Waging/Taching in Bavaria and artificially rained; response in the tile drains below the plots was measured. To identify direct flow we used NaCl as tracer. The tested variants were No Slurry (N), Conventional (P), Dribble Bar (SC), Trailing Shoe (SH), and Slit Injection (D). Results showed that up to 50 % of the applied surface water was connected as direct flow to the tile drains. All near ground application techniques exhibited a positive effect on P losses –this was a consequence of the different extents of wetting of the soil surface by the various application techniques. Our results show that pastures may exhibit a considerable amount of preferential flow paths which directly connect the soil surface to underlying drains thus enabling very rapid P (and other substances) transport into linear flow paths such as tile drains.

S12.05 -6

FIXATION OF PHOSPHORUS BY ADDING AMENDMENTS TO P SATURATED SOILS IN FLANDERS.

De Bolle Sara*^[1], De Neve Stefaan^[1]

^[1]Ghent University ~ soil management ~ Ghent ~ Belgium

As a result of decades of excessive phosphorus fertilization, most acid sandy soils in Flanders (Belgium) and the Netherlands are phosphorus (P) saturated. This saturation entails a risk of significant P leaching to groundwater and causing environmental problems. A study was done to test several amendments to the soil in terms of their potential in retaining P in the soil, thereby decreasing the P availability and the risk of P leaching. In this study several chemical amendments (such as CaCO₃, CaCl₂, AlCl₃, AlSO₄, FeCl₃, FeSO₄, olivine sand, ...) were evaluated on their ability to fix P in five different acid sandy soils, with different PSD, by a filtration and a leaching experiment. The idea is to get a better understanding in which amendments are most effective and to see if the same amendments perform equally as efficient in soils with different PSD. Out of first results came that chemical amendments seem promising in reducing the availability of P in P saturated soils.

REDUCING PHOSPHORUS LEACHING FROM DRAINED HEAVY CLAY SOIL

Ulén Barbro*^[1], Etana Araso^[2], Svanbäck Annika^[3]

^[1]SLU ~ Soil and Environment ~ Uppsala ~ Sweden ^[2]SLU ~ Soil and Environment ~ Uppsala ~ Sweden ^[3]SLU ~ Soil and Environment ~ Uppsala ~ Sweden

Abstract Eutrophication of waters with too much phosphorus (P) and nitrogen (N) from agricultural land is a serious problem. In a four-year plot experiment in the watershed of a drinking water reservoir, and soil with high clay content (60%), structure liming gave a distinct, significant reduction in P leaching via tile drains, mainly in the form of particulate phosphorus (PP), together with increasing yields of barley.. Overall, total phosphorus (TP) leaching (kg ha⁻¹) declined by 35-50%. Three years after structure liming the aggregate stability, expressed as readily dispersed clay (RDC), was still significantly improved for limed plots, with a turbidity value (FTU units) of 16 compared with 20 in non-limed plots. Omitting ploughing and only cultivating in autumn significantly increased PP leaching losses, but reduced nitrate-nitrogen (NO₃-N) leaching. The soil profile demonstrates a generally high ability to sorb P to the soil matrix and leaching losses of dissolved reactive P (DRP) was low from this site. Different strategies for mineral P fertilisation have not yet shown clear tendencies.

S12.05 -8

REMOVAL OF PHOSPHORUS FROM DRAINAGE WATER USING AN ENVELOPED PIPE DRAIN

Koopmans Gerwin F.^[1], Chardon Wim J.^[2], Groenenberg Jan E.^[2]

^[1]Wageningen University ~ Department of Soil Quality ~ Wageningen ~ Netherlands ^[2]Alterra ~ Soil Science Centre ~ Wageningen ~ Netherlands

In Dutch surface waters, phosphorus (P) concentrations are often too high and eutrophication is a major problem. Mitigation measures are needed which can contribute to improving the chemical surface water quality. The effectiveness of enveloping a pipe drain with iron-coated sand for reducing P losses was tested in a field experiment in the flower bulb growing region in the western part of The Netherlands. In this region, problems with P losses and surface water quality are large, and high P concentrations in pipe drain water are rather common. Iron-coated sand is a side product of drinking water production from anaerobic groundwater, and it exhibits a high P binding capacity and a high saturated hydraulic conductivity. In September 2010, a new pipe drain was installed at a depth of 0.8 m below the soil surface between two reference pipe drains, and enveloped with a layer of 10 cm iron-coated sand. Water samples were regularly collected from the effluents of the enveloped and the two reference pipe drains, the ditch which received all water from the field, and porous suction cups placed along the enveloped pipe drain. In addition, in situ measurements of pH and redox were done. Concentrations of amongst others dissolved reactive P, total dissolved P, and particulate P were measured. We will present results on the effectiveness of the enveloped pipe drain for reducing P losses by comparing the results of this measure with those of the two reference pipe drains.

^[1]Universität für Bodenkultur Wien (BOKU) ~ Department of Forest and Soil Sciences ~ Tulln ~ Austria

*Phytoextraction is a technology that uses plants and associated microbes for the removal of potentially toxic trace elements (TE) from contaminated soils. The efficiency of this approach depends on the concentration of TE in the harvestable biomass (i.e. shoot) and the amount of produced biomass. For soils with very large soluble TE concentrations an immediate risk of TE leaching into groundwater may require additional short-term measures, e.g. in situ immobilisation, with TE-binding soil amendments. Subsequent phytoextraction will afterwards remove the contaminants from the soil. Locally enhanced TE bioavailability in the rhizosphere will re-mobilise the previously immobilised TE fractions. This locally enhanced acidification might be caused by the phytoextraction plant, but in case of insufficient proton release, also by co-cropped plants which are known for their efficiency to acidify the rhizosphere (e.g. alders). Two acidic contaminated soils were treated with a mix of gravel sludge and red mud and later planted with *Salix x smithiana*, a Zn- and Cd-accumulating plant. To mimic the rhizosphere acidification by alders, elemental sulphur was added. The results show that although the solubility and bioavailability of Zn and Cd in soil was strongly reduced with the addition of the amendment, the phytoextraction efficiency of the willow was only slightly decreased. Soil acidification could significantly increase the Zn and Cd accumulation in plant. Our results show that the combination of in situ immobilisation with phytoextraction and its enhancement by soil/rhizosphere acidification is a promising approach for soils posing strong environmental risks due to high TE solubility.*

Mine-spoils and tailings present hostile environments for plant growth (low nutrients, low organic matter content, high acidity, elevated trace metal content). Phytostabilisation techniques aim to establish a vegetation cover and promote in situ inactivation of trace metals in this kind of environment by combining the application of soil amendments with the cultivation of metal-tolerant populations of plant species. In this study, field plots were established in Spring 2011 in an abandoned copper mine in NW Spain. The geological substrate is amphibolite, with significant quantities of metal sulfides (pyrite, pyrrhotite, and chalcopyrite). The mine-soils (Spolic Technosols (Episkeletic)) are characterised by their extreme acidity (pH 2.8-3.5), low C, N and P, and high concentrations of Cu (319-774 mg/kg). Three experimental plots (10mx45m) were established to evaluate three amendments and different metal-tolerant clones of Salix (S. caprea and S. viminalis) and Populus nigra. Amendments consisted of composted municipal solid wastes (compost) and two technosols. Technosols were mixtures of organic (anaerobic and aerobic sewage sludge) and inorganic wastes (aluminium oxides, iron oxides, fly ash from wood bark combustion, and foundry sand). Application rates of all amendments were equivalent to 250 kg Mg-1 dry tailings. Each experimental plot was sub-divided into 5m×5m sub-plots, and three replicate sub-plots were used for each plant species/clone. Soil samples were collected to determine the baseline trace metal content and general physico- and bio-chemical properties before amendment addition/planting. Results will be presented of plant growth/survival and soil properties (improvement in pH, nutrient availability and Cu bioavailability) one year after planting.

S12.06a -3

APPLICATION OF ORGANIC SECONDARY RAW MATERIALS FOR THE RECLAMATION OF DEGRADED SITES

Haubold-Rosar Michael*^[1]

^[1]Forschungsinstitut für Bergbaufolgelandschaften e.V. ~ Director ~ Finsterwalde ~ Germany

Sites degraded by over-exploitation and erosion are generally characterized by a severe loss of organic soil material or even the whole topsoil. Building and mining activities leave raw and partly artificial soils on earthworks, dumps and tips. A prior objective of land reclamation in such areas is to restore soils which will fulfill their functions as a habitat for plants and animals, as a production site for agriculture or forestry and as a regulator in the cycling of matter and water in the landscape. Herein the rapid formation and maintenance of a balanced humus and nutrient budget is of great importance. For this purpose organic secondary raw materials like compost may be conveniently used in the reclamation process as soil improving agents which contribute to a lasting development of a favorable humus and nutrient balance, structure and biological activity in those soils. The processing of organic residues for the creation of high quality organic soil improving materials will close material cycles and contribute to the value added in the regions. This should be an essential part of a sustainable material flow management. The paper will be based on results of research in the Lusatian mining region, Germany, carried out to determine the benefits of different applications of organic materials and to test the long-term environmental compatibility of such applications with regard to a possible contamination of soils, seepage water and plants, at least to work out quality criteria and recommendations for reclamation practice.

**CO-EVOLUTION OF SOILS AND LANDFORMS: PEDOGENESIS AND EROSION MODELLING
OVER DECADAL TIMESCALES FOR DISTURBED LANDS**

Willgoose Garry^{*[1]}, Hancock Gregory^[2], Cohen Sagy^[3]

^[1]The University of Newcastle ~ Civil, Surveying and Environmental Engineering ~ Callaghan ~ Australia ^[2]The University of Newcastle ~ Earth Sciences ~ Callaghan ~ Australia ^[3]University of Colorado ~ INSTAAR ~ Boulder ~ United States

Landform evolution models (LEMs) have become a routine tool for assessing the erosional stability of mine waste, tailings facilities, and low level nuclear waste facilities. LEMs have ignored temporal changes in the soils due to erosion, nor do they model pedogenesis. These changes in soils and erosion rates may be independent of (e.g. weathering of soils/rock particles), or dependent on (e.g. armouring due to selective entrainment) the fluvial erosion process. Typically, LEMs and traditional erosion models have implicitly assumed that soils are constant in time and at equilibrium. This is unlikely to be true for disturbed sites. Many of the mine and nuclear waste rehabilitation problems examined by the authors using LEMs show significant evolution of the surface erodibility at the yearly to decadal timescale. At some sites weathering of rock fragments is fast enough to interact with erosion and change the waste rock dump erodibility. We conclude that the evolution of soils must be modeled explicitly to be able to predict landscape evolution over the decadal timescale. In this way we can (1) model pedogenesis and co-evolving vegetated ecosystem dynamics and (2) erosion rates. Some insights based on our recent work in quantitative pedogenesis models will be presented and how pedogenesis can be incorporated into sustainability studies of waste dumps using LEMs. We will show that there are two important pedogenic timescales, (1) the surface of the soil and (2) the entire soil profile.

*The following work intends to present the experience developed at the test site of the abandoned mine of blend and galena of Ingurtosu (Sardinia, Italy), within the frame of the UMBRELLA Project (FP7, Grant No. 226870), aimed at using microorganisms to develop cost-efficient and sustainable measures for soil remediation at heavy metal contaminated sites, throughout Europe. Integrated investigations on (hydro)geochemistry, heavy metals concentration and mobility in soil, microbiology and botany provided a data set for the development of a tool-box to deliver a microbial assisted phytoremediation process. A bacterial consortium has been established with ten native bacterial strains, selected as the best performing, out of the total isolated, for heavy metal resistance and plant growth promotion (PGPB). Phytoremediation tests have been carried out-with endemic pioneer *Euphorbia pythiusa* - first in pot experiments and subsequently in a field trial, in order to assess the effectiveness of the bacteria, mycorrhiza and ViroMineTM products (limited to the field trial) on heavy metal leakage control. Microbial activity in soil, plant physiological parameters, heavy metal content in plants and in soil were monitored before and after the treatments. Integration of data sourced in pot experiment from biology (soil microbial activity, germination and plant growth parameters) showed that the bacterial bioaugmentation produced a general stimulation both of soil microbial activity and germination, shoots and roots elongation and photosynthesis. Changing in toxicologically relevant metals bioavailability - measured with a novel simple in field screening method- and the overall field trial outcome will be discussed.*

*Considering that environmental risk assessment based on the total concentration of a contaminant can overestimate risks, and that organisms respond only to its fraction that is biologically available, it is very important to understand if availability results obtained by chemical methods really translate into "biological availability" obtained by observing effects on organisms. This study aims to contribute to that discussion by comparing (bio)availability results, obtained by chemical methods, with those obtained by observing effects on organisms and by determining metal uptake and bioaccumulation by the exposed organisms. Soils from São Domingos Mine, an abandoned mine located in the Portuguese sector of the Iberian Pyrite Belt, were characterized considering: (i) general physicochemical characterization; (ii) pseudo-total and bioavailable trace element concentrations obtained by chemical extractions; (iii) ecotoxicological evaluation using the whole soil (seed germination with *Lactuca sativa* L., *Eisenia fetida* mortality and reproduction bioassays); and (iv) earthworm trace element concentrations, after 28 days of exposure to the contaminated soils. In the mine area, the soils were generally acid, poor in organic matter and in plant nutrients. Pseudo-total As, Cu, Pb and Zn concentrations were very high, and the same was true for their CaCl₂ 0.01 M extractable fractions. Regardless of the soil poor physicochemical characteristics, earthworm acute toxicity bioassay was unable to identify its toxicity, but the opposite was true for the reproduction bioassay using the same organism. Results obtained in the study are discussed in order to provide an insight into the question posed at the beginning of the experiment.*

^[1]K U Leuven ~ Soil and Water Management ~ Leuven ~ Belgium ^[2]Universidad Autónoma de Madrid ~ Agricultural Chemistry ~ Madrid ~ Spain ^[3]Universidad Autónoma de Madrid ~ Biology ~ Madrid ~ Spain

Derelict mine soils often pose environmental risks. In Spain, the soils of several derelict mines have to be reclaimed as a consequence of new legislation (in 2005). With the aim to establish a robust action plan in an old mine in Madrid, we studied the contamination in the field and the transfer of contaminants to native plants naturally growing there. We found high levels of As and Zn in soils, but the transfer of As to plants was low. The field study showed how natural attenuation occurs for As, while Cd and Zn are being effectively accumulated in some plant shoots, and that there are hot spots of contamination linked to the mine tailings. With our data, we modeled the environmental risk of transfer to organisms (soil organisms, aquatic organisms, livestock, mammals and avians). We found all the contaminants are likely to pose hazard for the ecosystem, mainly in the areas adjacent to the mine wastes. As a consequence, pot and batch experiments were carried out to select the best combination plant-amendment to manage the site. Fe oxides has given good results for As but may pose a risk of metal mobilization (Zn), organic matter restricted metal mobility but induced As solubility, and inorganic fertilization with P promoted excessive As leaching. Therefore, a combination of both is being tested in pots and lysimeters. Eventually, we expect to give a management recommendation that minimizes undesirable effects.

GEOCHEMICAL ASSESSMENT OF THE MIXTURE OF TAILINGS AND WASTE ROCK WITH AMENDMENTS (LIME AND BENTONITE) FOR A WATER-SHEDDING COVER ON MINE WASTES

Zhao Lu^{*[1]}, Baumgartl Thomas^[1], Edraki Mansour^[1]

^[1]Centre for Mined Land Rehabilitation (CMLR) ~ Sustainable Minerals Institute (SMI) ~ Brisbane ~ Australia

Waste rocks and tailings produced through mining activity are often in direct contact with the environment and can potentially be major sources of acid and metalliferous drainage, containing multi-elemental contaminants. Required remediation strategies try to incorporate locally available solid materials (dry tailings and waste rocks) mixed with amendments, such as lime and clay material, to control water infiltration and oxidation processes. The objectives of the study were to characterise the geochemistry of selected materials for the construction of a water-shedding cover for mine wastes, and to assess the potential release of acid and metalliferous drainage from such constructed cover. A column experiment was carried out with two types of tailings (particle size smaller than 2 mm) and one waste rock (particle size smaller than 19 mm) mixed with 10% or 20% of amendments (lime and bentonite). The pH, EC and dissolved metal concentrations in leachate were measured over time with dry and wet cycles. Particle size influenced the water retention time and consequently the concentrations of metals. The mixture of tailings and lime produced minimum amount of soluble metals in leaching, which was a more effective approach despite of the high pH (more than 12); bentonite did not reduce metal leaching from tailings but increased the water content in the waste rock. Our results show the effects of amendments from both physical and chemical aspects. Application of this concept will allow a better understanding of material performance under conditions of wetting and drying as part of the natural climate variability.

S12.06b -4

**CHANGES IN MICROBIAL COMMUNITY STRUCTURE LINKED TO ORGANIC AMENDMENTS
IN RECONSTRUCTED SOILS.**

Beasse Mark^[1], Quideau Sylvie^[1]

^[1]University of Alberta ~ Renewable Resources ~ Edmonton, Alberta ~ Canada

Landscape scale reclamation of upland forests in the Athabasca oil sands regions of north-eastern Alberta, Canada, utilizes peat as an organic soil amendment due to shortages in forest floor, the organic material native to these target ecosystems. Considering the differences in physical and chemical properties between these two materials, there is a concern that using peat will fail to recreate the diverse interactions within the soil microbial community consistent with the target ecosystems. This study investigates the differences in microbial community structure and activity between forest floor, peat and mixtures of both at differing water contents and pH values using phospholipid fatty acid analysis and basal respiration. Indicator species analyses demonstrated that 10 of the 70 lipids analysed progressively changed in indicator values across treatments, 5 of which remained constant when the pH of the peat treatment was adjusted to near that of the forest floor. Basal respiration was significantly higher in the forest floor than peat treatments. While forest floor basal respiration varied in response to differences in water content, no differences were detected in peat treatments among the different water contents or between the natural peat and pH adjusted treatments. These results provide evidence that the physical and chemical characteristics of the organic matter types are related to the expression of specific segments of the microbial community. These further suggest that the sole use of peat as an organic amendment in reforestation scenarios is unlikely to provide the microbial community consistent with the target plant community.

S12.06b -5

RECLAIMED LIGNITE MINING AREAS IN LUSATIA – DEVELOPMENT OF SOIL PHYSICAL PARAMETERS OF AN AGRICULTURAL SITE WITHIN THE FIRST YEARS AFTER THE CONSTRUCTION

Kruemmelbein Julia^{*[1]}, Raab Thomas^[1]

^[1]Brandenburg University of Technology ~ Chair of Geopedology and Landscape Development ~ Cottbus ~ Germany

In Lusatia, lignite mining induces major disturbances on the landscape scale. Reclamation procedures are applied to recover the reconstructed landscape for different land use options. In this study we investigate soil physical properties of an agricultural reclamation/recultivation site directly after site construction and the development of selected parameters within the first years after site construction depending on varying recultivation strategies. The sandy substrates used for recultivation stem from depths of several meters. They are unstructured, free of recent organic matter and have high contents of calcium carbonate. During reconstruction and most of all during surface levelling with heavy crawlers the substrate undergoes strong mechanical stresses. This leads to partly severe soil or substrate compaction, depending e.g. on strata water content and mechanical stresses during site construction. We investigate the effect of different organic soil amendments, different crop rotations and partly sub soiling on the development of soil structure. We compare results of laboratory measurements directly after site construction before any recultivation measures had been applied to results we gained after three and four years of recultivation. The results show that the site is strongly heterogeneous concerning its mechanical stability, its permeability for air and water as well as pore volume and bulk density directly after site construction. The results after three and four years show that the heterogeneity of soil physical parameters decreases. The selection of suitable crop rotations superimposes the effects of other recultivation measures, e.g. varying organic fertilizers or deep loosening.

*Panasqueira mine located in the north centre of Portugal is still operating, being one of the main European tungsten producers. Tungsten, tin and copper have been exploited for over a century. The main environmental concerns for this site comes from the active and old huge tailings, acid mine generation and the water treatment plant. The objective of this study was to evaluate the biogeochemical impact of the mine activity in soils, mainly developed on old waste materials, and strawberry tree (*Arbutus unedo*) growing on these soils. The potential danger for strawberry tree fruits and the derived alcohol for human's consumption were also assessed. Soils developed on waste materials and soils influenced by mine drainage present variable concentrations (mg/kg) of As (158-7790), Cd (0.6-79), Cu (51-4080), W (19-1450) and Zn (142-12300). The available fraction concentration of the elements, extracted with DTPA, is quite variable depending on the element. Soils are mainly silty loam, acidic (pH (mean) ~5) with a wide range of Corganic (5.2-93.4 g/kg). Plants (branches and leaves) present, in some samples, concentrations (mg/kg) above the normal range for plants in general (maximum: As-5; Cd-13; Zn-570) but no signs of toxicity were observed. *Arbutus unedo* is a tolerant species but not trace elements accumulator. The strawberry tree fruits are not contaminated and can be used to produce local liquor. The concentration of the chemical elements in alcohol is within the range of the European legislation. The fruits consumption do not constitute risks (nephrotoxicity) for human health (Hazard Quotient <1).*

^[1]Norwegian Geotechnical Institute (NGI) ~ Environmental department ~ Oslo ~ Norway ^[2]Research Center for Eco-Environmental Sciences (RCEES) ~ Department of Soil Environmental Science ~ Beijing ~ China ^[3]Norwegian University of Life Sciences (UMB) ~ Department of Plant and Environmental Sciences ~ Ås ~ Norway

In the present study we investigated the behavior of Sb in flooded paddy soil sampled downstream an active Sb mining area in Xikuangshan, located in Hunan Province (China). Rice (Oryza sativa L. cv Jiahua) was grown under controlled conditions, and soil pore water concentrations and speciation of Sb were monitored during 50 days to study the effect of flooding, nutrient addition and rice plants. Results were compared with behavior and uptake of arsenic (As). Flooding the paddy soil (no rice plants) increased both the concentration of Sb and As, most likely due to increased pH and subsequent decrease in positive charge on oxides and clay minerals and reduced anion sorption capacity. Phosphate supply, in form of fertilizer, led to an initial increased Sb and As mobilization caused by the competition for the same sorption sites. When rice was present, Fe plaque developing on rice roots acted as a scavenger for both As and Sb, whereby the concentration of As, but not Sb, in porewater decreased substantially. Sb occurred mainly as Sb(V) in the porewater, and a strong negative correlation between Sb(V) and calcium (Ca) concentrations in porewater indicated a Sb solubility governed by Ca antimonate. Greater relative concentration of Sb(V) was found in rice shoots compared to rice root and porewater, indicating either a preferred uptake of Sb(V) or possibly an oxidation of Sb(III) to Sb(V) in shoots. No significant differences in bioaccumulation factor and translocation factor between Sb and As were observed.

USE OF THE COMPUTER MINTEQ MODEL TO WATERS AFFECTED BY MINING ACTIVITIES: A PARTICULAR CASE IN SE SPAIN

Martínez-Sánchez Maria Jose^[1], Garcia -Lorenzo Maria Luz^[2], Perez- Sirvent Carmen^{*[1]}, Hernandez-Cordoba Manuel^[3]

^[1]University of Murcia ~ Agricultural Chemistry, Geology and Pedology ~ Murcia ~ Spain ^[2]Complutense University of Madrid ~ Petrology and Geochemistry ~ Madrid ~ Spain ^[3]University of Murcia ~ Analytical Chemistry ~ Murcia ~ Spain

Trace elements contained in the residues from mining and metallurgical operations are often dispersed by wind and/or water after their disposal. Water pollution by dissolved metals in mining areas has mainly been associated with the oxidation of sulphide-bearing minerals exposed to weathering conditions, resulting in low quality effluents of acidic pH and containing a high level of dissolved metals. According to transport process, three types of pollution could be established as a result of metal extraction. The aim of this work was to study trace element in water samples affected by mining activities. In addition, MINTEQ model was applied for calculating aqueous geochemical equilibria in water samples. Primary contamination: Sampling point S1 is located in a tailing dump and showed high trace element content. In addition this point is located close to the sea, and then, chloride, bromide, sodium and magnesium content is high. MINTEQ simulation suggested that soluble zinc content could precipitate as a carbonate (hidrozincite and smithsonite), just as manganese (rhodocrosite) and cadmium (otavite). Secondary contamination. Points affected by secondary contamination receive dissolved and particulated materials from Lo Poyo tailing dump and also receives trace element from surrounding soils (calcic Luvisols). Sea influence could be confirmed by chlorides, bromides, sodium and magnesium content also and also showed nitrates from agricultural soils located in topographically higher areas- Tertiary contamination: Water samples collected showed basic pH, soluble carbonates and low trace element concentrations. MINTEQ results suggested Cd, Zn and Mn could precipitate as carbonates, while aluminium would do it as oxihydroxide.

MODELLING BACKGROUND CONCENTRATIONS OF POTENTIALLY HARMFUL ELEMENTS FOR EVALUATION OF ANTHROPOGENIC CONTAMINATION: FOCUS ON CALCAREOUS SOILS IN THE SOUTH-WEST OF FRANCE

Redon Paul-Olivier^[1], Thomas Bur^[1], Maritxu Guiresse^[1], Jean-Luc Probst^[1], Aurore Toiser^[1], Jolivet Claudy^[2], Jean-Claude Revel^[1], Anne Probst^[1]

^[1]CNRS/UPS/INPT/ENSAT ~ EcoLab ~ Castanet-Tolosan ~ France ^[2]INRA ~ InfoSol ~ Orléans ~ France

Determining natural background concentrations of potentially harmful elements (PHE) in soils is difficult since these elements undergo many complex processes, both pedo-geogenic and anthropogenic. PHE concentrations observed in soil samples are resulting from: (1) atmospheric deposition, mineral weathering, migration along the soil profile (depending on the investigated element, the soil type and the environmental conditions) and (2) enrichment by exogenous deposition, mainly due to diverse human activities. We explore a dataset from cultivated soils (RMQS, French Soil Monitoring Network, Midi-Pyrénées region, S-W of France) to model adequately the background concentrations of As, Cd, Co, Cr, Cu, Mo, Ni, Pb, Sn, Ti, Tl, V, Zn. Different methods were investigated using a range of soil properties in order to identify anthropogenic contaminations. Descriptive statistics, enrichment factor and multiple linear regressions were used for diagnosis purpose. A discussion about the most suitable method is proposed. A confrontation with land use and agricultural practices at each studied site also allows the identification of potential contamination sources. Many contaminations were detected but of low intensity; a PCA is used to discriminate different groups of metals fates in soils. In this French region, a large proportion of soils are alkaline because of their formation on sedimentary calcareous bedrock. Indeed, typical related behaviours of PHE are poorly documented since such soil types are not so frequently investigated worldwide. Actual fates of PHE in alkaline soils are not very well predicted by current models. This needs improvement for decision about local risk assessment and agricultural soil management.

QUANTIFYING THE SPATIAL DISTRIBUTION OF HEAVY-METAL SOIL POLLUTION IN ELBASAN, ALBANIA, VIA PORTABLE X-RAY FLUORESCENCE

Perroy Ryan^[1], Sallaku Fatbardh^[2], Tota Odeta^[2], Hill Brian^[1]

^[1]University of Wisconsin-La Crosse ~ Geography and Earth Science ~ La Crosse ~ United States ^[2]Agricultural University of Tirana ~ Agriculture and Environment ~ Tirana ~ Albania

We used a portable X-ray fluorescence detector and a high-resolution GPS system to determine the spatial distribution of heavy-metal soil contamination in and around a large communist-era industrial metallurgy complex situated along the Shkumbini River in central Albania. Over 2500 geo-referenced samples were collected and measured over a 5-week period in the summer of 2010. In-situ surficial contamination levels of Cr (>300,000 ppm), Ni (>66,000 ppm), Cd (>3,000 ppm), and Pb (>110,000 ppm) were measured within the ~ 4 km² metallurgy complex, values supported by confirmatory ICP and other digestion analyses. Highly elevated soil contamination levels were also found in surface and sub-surface samples collected from residential areas, urban parks, roadsides, and agricultural fields in the surrounding area. Although large state ore-processing activities halted following the upheaval of the communist regime in 1997, new foreign-owned businesses and small scale Albanian land-holders and squatters now use the industrial complex area for housing, agriculture, livestock grazing, and new industrial activities like scrap-metal smelting. High-resolution maps of heavy metal soil contamination produced as a result of this work provide valuable knowledge of the magnitude and spatial distribution of these contaminants, as well as baseline data for understanding the associated ecological and public health impacts on surrounding and downstream communities.

THE INFLUENCE OF COMPOST APPLICATION ON SOIL VULNERABILITY TO HEAVY METAL POLLUTION

Rosen Vasiliy^{*[1]}, Chen Yona^[1]

^[1]Faculty of Agriculture, Food and Environment, Hebrew University of Jerusalem ~ Department of Soil and Water Sciences ~ Rehovot ~ Israel

Soil vulnerability may be defined as the soil's capacity to hold and release various contaminants and pollutants. The less vulnerable soils are those with high but finite capacities for storage of potentially mobilizable and harmful chemicals, particularly heavy metals. We propose to evaluate soil vulnerability to heavy metal pollution based on its ability to retain metals in forms which exhibit low phyto-availability. These geochemical forms can be defined as geochemical fractions following sequential extraction procedures. The fractions studied are listed below from the most to the least bioavailable ones: water-extractable (WE), exchangeable-adsorbed (EXC), associated with carbonates (CARB), occluded by reducible (hydro)oxides of Fe and Mn (RO), associated with organic matter (OM) and a residual fraction (RES). Chinese cabbage plants were grown in pots with soils and soil:compost mixtures spiked with soluble metal salts (Cd, Cu and Pb). The highest compost doses (72 and 115 Mg ha⁻¹) enhanced cabbage yield significantly. No excessive phyto-accumulation of metals has been observed in plants grown on the clayey soil and its mixtures with compost. The compost dose of 72 Mg ha⁻¹ was optimal in decreasing Cu accumulation by plants grown on the sandy soil, and 28.8 Mg ha⁻¹ was found to be effective in reducing Cd and Pb uptake. Metals were accumulated in plants primarily from the WE, EXC and CARB fractions, while other fractions decreased phyto-accumulation. Compost addition suppressed heavy metal mobility but different fractions were active in pollutant sorption depending on soil type and metal.

POTENTIALLY HARMFUL ELEMENTS IN THE FOOD CHAIN: TRANSLOCATION FROM SOIL TO PLANTS AND FOODSTUFF

Fontana Silvia^{*[1]}, Bini Claudio^[1], Vannuzzo Lisa^[1], Wahsha Mohammad^[1]

^[1]University of Venice ~ Environmental Sciences ~ Venice ~ Italy

In recent years great attention has been paid on the presence of PHEs (potentially harmful elements) in soils employed for food or feed production. The main sources of these pollutants in agroecosystems are: industrial and mining activities, vehicular traffic along major roads, use of fertilizers and pesticides, amendment with sewage sludge. The contaminants enter the soil system, and can be absorbed by humans through several paths: dermal contact, inhalation, soil particle ingestion, ingestion of contaminated crops. In this work we focus on the absorption of potentially harmful elements through the food chain, and in particular on PHEs' plant uptake from soil through the root system and translocation to the aerial parts. The study area is located in the proximity of an industrial district (mainly tannery industries, but also chemical industries and smelters) and along a highway in North-East Italy. Five transects parallel to the highway were sampled (totally 22 sampling sites). For each location, the following samples were collected: topsoil (0-20 cm), subsoil (45-70 cm), maize and wheat (approximately 20 plants for each sample). The following potentially harmful elements were determined by ICP-OES after complete acid digestion: Al, Fe, Mn, Cr, Pb, Ni, Zn, Cu. The area is slightly contaminated by Cr, Ni and Cu, but there seems to be any health risk due to food consumption, being these elements substantially immobilized in the roots. Wheat seems to behave as an excluder species in relation to most PHEs considered in this study, especially the non-nutrients.

TRACE METAL CONTENTS OF CROATIAN SOILS: REGIONAL DIFFERENCES AND EFFECT OF

Romic Marija*^[3], Bakic Helena^[4]

^[1]University of Zagreb ~ Faculty of Agriculture ~ Zagreb ~ Croatia ^[2]University of Zagreb Faculty of Agriculture ~ Dept. of Amelioration ~ Zagreb ~ Croatia ^[3]University of Zagreb Faculty of Agriculture ~ Dept. of Amelioration ~ Zagreb ~ Croatia

^[4]University of Zagreb Faculty of Agriculture ~ Dept. of Amelioration ~ Zagreb ~ Croatia

Soil survey on trace metals in agricultural soils of Croatia was carried out to assess soil quality, determine management and land conversion elements, and based on that assess risk of toxic element spreading into environment, first of all into groundwater and surface water bodies. A multi-element geochemical survey consists of soil sampling from 1294 locations covering the Croatian territory (56.594 km²) from the two depths. The following soil properties were retained: (i) element concentrations determined by ICP-OES after aqua regia dissolution, (ii) the TOC measured by dry combustion, (iii) the particle-size distribution using wet sieving and the pipette method, (iv) CEC and exchangeable cations (BaCl₂ method), (v) pH and ECe, (vi) "labile pool" trace metals and nutrients (CaCl₂ extraction). A GIS geochemical database was compiled followed by statistical and geostatistical analyses and mapping. Geomorphologically, Croatia is divided into three main regions, each of which having specific climate, geology, hydrology, soil types and land use. The spatial variability and baseline of elements in soils separately for different regions were determined applying multivariate geostatistics. The influence of natural conditions on regional differences was observed, and the apportionment of natural vs. anthropogenic contribution to trace metals soil accumulation was assessed, as well.

TRACE ELEMENT TOTAL CONTENT AND BEHAVIOR IN FOREST SOIL OF SOUTHERN QUÉBEC, CANADA

Masse Jacynthe*^[3], François Courchesne^[2]

^[1]University of British Columbia ~ Forest Science ~ Vancouver ~ Canada ^[2]Université de Montréal ~ Département de géographie ~ Montréal ~ Canada ^[3]University of British Columbia ~ Forest Sciences ~ Vancouver ~ Canada

Forest soils represent a considerable stock of nutrients available to sustain forest productivity. They also contain a trace elements (TE) pool of unknown size. Since many of these trace elements can be toxic, quantifying the concentration and the total content of TE in forest soils is necessary to assess their impact on soil quality. The specific objectives of this project were: 1) to measure the concentration and the total content of TE in the solid phase of the various soil horizons from two forest ecosystems in southern Quebec and 2) to unravel the associations existing between the bioavailable TE fraction and soil horizon properties. To achieve these goals, four soil profiles, two situated in a protected forested area (St-Hippolyte, Québec) and two from the urban area of Montréal, were excavated down to the parent material, sampled on a horizon basis, and analyzed for TE using ICP-MS. We found that the main pool of total TE is concentrated in coarse fragments of the soil. Conversely, the bioavailable TE fraction resides mainly in the organic horizon of the studied profiles. Multivariate statistical analyses revealed that, organic carbon, Fe-Al oxides, and amorphous forms of Si explained the vertical distribution of TE in soil profiles. By quantifying total TE reserve in the sampled soils, this project increases our understanding of the factors controlling spatial heterogeneity in TE in southern Quebec soils, and allows for better understanding of the role of soils in the biogeochemical cycle of TE in terrestrial ecosystems

TIME SERIES OF HEAVY METAL AND RARE EARTH ELEMENT ACCUMULATION IN TOP SOIL OF A LONG-TIME P FERTILIZATION EXPERIMENT

Smidt Geerd^[1], Iliev Milen^[2], Schnug Ewald^[3], Koschinsky Andrea^[1]

^[1]Jacobs University Bremen ~ Integrated Environmental Studies ~ Bremen ~ Germany ^[2]University of Bremen ~ Departement of Geosciences ~ Bremen ~ Germany ^[3]Technical University Braunschweig ~ Department of Life Sciences ~ Braunschweig ~ Germany

Mineral fertilizers with a phosphorus component contain numerous heavy metals in wide concentration ranges. In products traded in Germany average concentrations of up to 19.3 mg As kg⁻¹, 25 mg Cd kg⁻¹, 53.7 mg Cu kg⁻¹, 27.4 mg Ni kg⁻¹ and 280 mg Pb kg⁻¹ and 97.5 mg U kg⁻¹ were found. While fertilizers processed from sedimentary rock phosphates are enriched in heavy metals and radionuclides, products derived from igneous sources contain 10 times higher concentrations of rare earth elements (REE, e.g. 0.1 % La and 0.15 % Ce). In our study, we investigated the accumulation of the named elements in top soils of a long-time fertilization experimental field as a function of fertilization rates and application time. The fertilization experiments started in 1983 and the 6 different treatments received annual P₂O₅ applications between 0-510 kg ha⁻¹. Differences between the initial (1983), intermediate (1995) and recent (2011) heavy metal and REE concentrations in soil samples from the different plots will be presented. Furthermore, it will be tested if REE patterns of highly fertilized top soils show coherences with the unique REE pattern of P fertilizers of marine sedimentary origin, which are preferentially (87 %) used in Germany.

ASSESSING THE EFFECTS OF INCREASING SOIL ANTIMONY CONCENTRATIONS ON PLANT GROWTH: AN OVERVIEW

Jelle Mertens*^[1]

^[1]International Antimony Association vzw (i2a) ~ ~ Brussels ~ Belgium

*Effects of antimony on plant growth have been extensively reviewed and studied in the EU Risk Assessment Report (2008) on diantimony trioxide (ATO). Readily soluble Sb compounds (such as antimony trichloride, ATC) have been frequently used as test substance. Yet, addition of these substances also affects the soil solution chemistry (release of counter ions/protons/...) next to Sb concentrations complicating data interpretation; the NOEC and EC10 for lettuce (*Lactuca sativa*) shoot yield in ATC spiked soil were 0.4 and 2.7 mmol Sb/kg, but effects were entirely explained by the increasing chloride concentrations. Alternatively, ATO has been used (no release counter ions, no effects on soil pH), but most studies reveal unbounded threshold concentration (no effects observed at the largest Sb dose) due to slow dissolution kinetics of ATO. It was agreed at EU-level that sufficient ageing needs to be applied to allow the release of Sb ions and, as such, overcome an increasing 'toxic pressure' over time. A study was performed using 31-weeks aged ATO spiked soils (0-83 mmol Sb/kg). Sb effects on plants were assessed using the barley (*Hordeum vulgare*) root elongation and lettuce shoot yield assay. The former assay was most sensitively affected with a NOEC and EC10 of 8.2 and 16 mmol Sb/kg, or 80 and 110 $\mu\text{mol Sb/l}$ on a soil solution base. Effects were solely attributed to increased Sb concentration; soil pH, soil solution metal concentrations (except Sb) and ionic strength remained constant with increasing Sb dose. Latter data are used in the EU regulatory context.*

ASSESSING EXPOSURE TO CADMIUM IN A METAL RECYCLING COMMUNITY IN VIETNAM

Minh Ngo^[1], Hough Rupert^{*[2]}, Thuy Le^[1], Nyberg Ylva^[3], Mai Le^[4], Vinh Nguyen^[1], Oborn Ingrid^[3]

^[1]Soils & Fertilizers Research Institute ~ Vietnam Academy of Agricultural Science ~ Hanoi ~ Viet nam ^[2]The James Hutton Institute ~ Informatics and Computational Sciences ~ Aberdeen ~ United Kingdom ^[3]Swedish Agricultural University (SLU) ~ Department of Soil Sciences ~ Uppsala ~ Sweden ^[4]Hanoi University of Science ~ Faculty of Environmental Science ~ Hanoi ~ Viet nam

In Vietnam, human susceptibility to trace metals, in particular Cd, has specific gender and wealth aspects. Levels of iron (Fe), zinc (Zn) and calcium (Ca) in rice are insufficient for human needs. Further, polishing rice grain causes further Fe and Zn losses whilst levels of Cd in grain remain unaffected by this process. Iron deficiency predisposes individuals to a higher Cd absorption and therefore women are a more vulnerable group since they are more prone to Fe deficiency (anaemia). In 1995, 40% of Vietnamese women between 15 and 40 yrs were considered anaemic. In 2004, the national average has through an effective Fe supplementation program declined to 28%. However, for pregnant women, the percentage with anaemia was still high (34%). In order to estimate risks to specific population sub-groups (age, gender, socio-economic status), self-reported questionnaire data are being used to link measured concentrations of metals to exposure via contact with soils, the environment, and through consumption of rice. The project will provide local communities and authorities with background data to support improvement and implementation of policies related to environmental and food safety.

De Vivo Benedetto^{*[1]}, Albanese Stefano^[1], Lima Annamaria^[1], Rezza Carmela^[1], Ferullo Giampiero^[1], Chen Wei^[2], Qi Shihua^[2]

^[1]Università degli Studi di Napoli Federico II ~ Dipartimento di Scienze della Terra ~ Napoli ~ Italy ^[2]China University of Geoscience ~ School of Environmental Studies ~ Wuhan ~ Canada

In the framework of the URGE (Urban Geochemistry) project aiming at depicting the environmental conditions of several cities in Europe, the north-eastern sector of the Naples metropolitan area (Italy), namely the Acerra-Pomigliano-Marigliano area (with ~130.000 inhabitants), has undergone a geochemical characterization based on topsoil sampling (145 samples over an area of 90 sqkm). This area has been selected because of both the presence of an historical industrial settlement on it (mainly devoted to plastic materials and synthetic fibres production) and of an incinerator which came into operation in March 2009. The main objective of the study is to define the local geochemical baselines both for 53 elements (among which the toxic ones) and for some organic compounds, including Dioxins and Furans. Furthermore, the study aims to support epidemiological researches and to establishing a record of the environmental status quo to evaluate in the future the impact of the incinerator on both territory and population. First results show that the most urbanized areas of the Acerra-Pomigliano-Marigliano conurbations are characterized by concentrations of Pb, Zn and V exceeding the intervention limits established by the Italian Environmental law (D.Lgs. 152/2006). Agricultural soils, in the surroundings of the urbanized areas, are enriched in Cu, Co, Cd, Be and Ni, and the probable presence of illegal waste disposals in the area could be considered as a source for them. In the area where the incinerator has been built Se, Hg, Cu, Cd and Sb baselines are generally higher than in the rest of the territory.

S12.07c -2

MECHANISMS OF REALIZATION OF POTENTIALLY DANGER OF MICROELEMENTS

Motuzova Galina*^[1]

^[1]Moscow State University ~ Faculty of Soil Science ~ Moscow ~ Russian Federation

Microelements (ME) - one of the most important groups of elements in the environment. Their low quantity is necessary for living organisms. At the same time they present potentially harmful elements. Their danger can be realized when the content of microelements in environment increases. The mechanisms of the realization of their danger are specific for every sphere. As far as soils, high content of microelements (including metals) in soils provides the changes of two groups of soil properties: the state of metals and some important chemical properties of soils. The results of laboratory and field investigations have shown the mechanisms of such changes. In soils, polluted by different metals, the share of their mobile species always increases and it provides the negative influence of the polluted soils on plants, on natural water. Simultaneously the negative changes of the important chemical properties occur. The changes in the state of soil organic matter take place as a result predominantly of the formation of their complexes with ions of the added metals. These processes lead to the restructuring of organic components, including the separation of some fragments from the molecules of humus acids. These processes are accompanying by the additional acidification of liquid phases of soils and by decreasing of cation-exchangeable ability of soils. The properties of clay minerals also can change under the influence of metals excess in soils. The degradation of soil components under the influence of excess of microelements leads to decrease of stability of soils to pollution.

The ecodynamic of As, Cr, Cu and Zn was studied in phytomanaged soils contaminated with levels of Cu from a former wood preservation site (Bordeaux, FRANCE). This alluvial sandy soil is managed with natural attenuation, assisted management (organic matter, dolomite), phytoextraction (sunflower) and present an increasing level of Cu contamination by patches in the same site. This study aims at obtaining data on the concentrations and speciation of trace elements (TE) in the water-soil-plant system and on the soil reaction mechanisms for the TE. Biotests (dwarf beans) were carried out on soil sampled from the site as well as physico-chemical characterisation of the soils and trace metal speciation (Rhizon, DGT). This experimental set-up was applied on two years to monitor the effect of amendments and the increasing concentrations of Cu on the dynamics of the TE in this soil. Effect of increasing concentrations of Cu on the mobility/availability of TE to the plants and microorganisms of the soil, effects of dissolved organic compounds in the solution of soil on the speciation and the fixation of TE on the organic/inorganic colloids and TE impacts and bioaccumulation in plant communities were investigated. Preliminary results showed that the high concentrations of Cu in the phytomanaged soils treated with organic matter and dolomite inhibited the mobility and the availability of other TE in the soil.

DETERMINISM OF THE SPATIAL DISTRIBUTION OF METALLIC TRACE ELEMENTS CONCENTRATIONS IN SOILS CONTAMINATED BY ATMOSPHERIC FALLOUTS: THE CASE OF THE SCLAIGNEAUX AREA (BELGIUM)

Liénard Amandine^{*[1]}, Dère Christelle^[1], Colinet Gilles^[1]

^[1]University of Liege - Gembloux Agro-BioTech ~ Sciences et Technologies de l'environnement ~ Gembloux ~ Belgium

The valleys of Sambre and Meuse in Wallonia hosted numerous metal ore treatment factories. They engendered a contamination of soils by metallic trace elements that may migrate in the landscape through erosion, lixiviation, biological transportation, aso. We investigated the spatial distribution of some metallic trace elements in soils around a former zinc-ore treatment plant to a distance of 3km. The sampling strategy aimed at (i) verifying that the main source of trace elements was the plant chimney, (ii) assessing the impact of the wind directions on fallout dispersion and (iii) evaluating whether there were differences of contents according to soil types and to soil occupation. Two hundred and fifty topsoil samples were collected according to a stratified design dealing with distance to the chimney, direction of dominant winds, soil type, and land use. Pseudo-total contents in inorganic elements, pH, TOC, and N were determined in the laboratory. Besides, classical statistical analysis (i) ANCOVA (three-way ANOVA with the distance as a co-variate) and (ii) Principal Component Analysis were also performed. First results show that (i) zinc, lead and cadmium contents are closely correlated to each other and (ii) negatively correlated with the distance. If the geographical location is the major driving factor of trace elements contents in soils, significant differences were also found between soil type and land use ($p\text{-value} < 0.05$). The highest MTE concentrations were associated with North-East winds, forest cover and pebbles rich soils. Further investigations will concern the vertical and toposequential distributions, and the speciation of MTE.

TESTING OF INORGANIC AND ORGANIC AMENDMENTS FOR IN SITU STABILIZATION OF CD, CU & ZN IN A STRONGLY CONTAMINATED KASTANOZEM

Jung Stephan^[1], Thomas Hanauer^[2], Sven Schubert^[1], Peter Felix-Henningsen^[2], Diedrich Steffens^[1]

^[1]Justus Liebig University Giessen / Research Center for BioSystems, Land Use and Nutrition ~ Institute of Plant Nutrition ~ Giessen ~ Germany ^[2]Justus Liebig University Giessen / Research Center for BioSystems, Land Use and Nutrition ~ Institute of Soil Science and Soil Conservation ~ Giessen ~ Germany

The objective of our project was the *in situ* remediation of a Kastanozem in Georgia highly polluted with Cd, Cu and Zn. A pot experiment with a top soil of this region was conducted at Justus Liebig University Giessen, Germany. Four soil amendments were applied: elementary iron (Fe⁰), natural zeolite, Divergan® (a synthetic polymer) and a biochar product. Each amendment was applied in various concentrations to 4 kg of contaminated soil. The soil was moistened and incubated in a growth chamber for 5 weeks. After this time spinach (*Spinacia oleracea* L.), vegetable rape (*Brassica napus* L.), wheat (*Triticum aestivum* L.) and again spinach were cultivated in the timeframe of one year. In all treatments 1 M NH₄NO₃-extractable Cd was reduced compared to the control treatment. The strongest effects on the reduction of 1 M NH₄NO₃-extractable Cd, Cu and Zn were measured in the Divergan® treatments. Furthermore a 7-step sequential extraction confirmed a shift from easily mobilizable to heavily bound fractions. Application of the soil amendments increased plant growth in most cases, most likely due to a reduction of Cu and Zn toxicity. The plants in the control treatment always showed Cd concentration above EU threshold values. The Cd concentration in plant tissue was mostly decreased below these thresholds in the Divergan® treatment. In conclusion, Divergan® seems to be a useful amendment for *in situ* immobilization of Cd, Cu and Zn- polluted soils.

THE INFLUENCE OF BIOGEOCHEMICAL AND PHYSICAL SOIL PROPERTIES ON THE NATURAL VARIABILITY OF SELECTED HEAVY METALS – A GEOCHEMICAL SOIL SURVEY OF CONTINENTAL EUROPE

Guicharnaud Rannveig Anna*^[1], Montanarella Luca^[1]

^[1] Joint Research Centre (JRC), Institute for Environment and Sustainability (IES) ~ Land Management and Natural Hazard Unit ~ Ispra ~ Italy

Heavy metals (HM) in soils can directly influence human health via the food chain and have hence become an important factor in terms of determining soil quality. The mobility and bioavailability of HM in the environment depends on the total concentration of the elements but also on soil physical and biogeochemical properties. Soils are generally long term HM sinks and HM have been found to accumulate in organic layers and clay rich layers of forest soils. Geochemical soil surveys on natural variability and distribution of HM can play an important role in assessing environmental quality. Here, we present the results from the BIOSOIL forest soil survey conducted on 12 forested soil types (WRB) in 33 European countries. A special emphasis was placed on assessing the influence of biogeochemical and physical soil properties on the accumulation of HM in organic and mineral layers in both top and sub soil horizons. Land use changes can affect accumulation of HM in soils and in turn soil fertility and ground water quality. Monitoring of HM in different management systems can provide a theoretical base for controlling soil HM concentrations. An additional land survey has therefore been launched by combining the BIOSOIL to the LUCAS-soil, a pilot project to monitor changes in land management, where 1/3 of forest sample points were transferred to arable and grassland in 25 EU countries.

ASSESSING THE EXPOSURE OF SOIL ORGANISMS TO PESTICIDES IN THE EUROPEAN UNION

Tiktak Aaldrik^[1], Boesten Jos^[2], Klein Michael^[3], Vanderborght Jan^[4]

^[1]PBL Netherlands Environmental Assessment Agency ~ WLV ~ Bilthoven ~ Netherlands ^[2]Wageningen UR ~ Alterra ~ Wageningen ~ Netherlands ^[3]Fraunhofer Institute ~ Biology and Applied Ecology ~ Schmallenberg ~ Germany ^[4]Forschungszentrum Jülich GmbH ~ Agrosphere, ICG-4 ~ Jülich ~ Germany

EFSA developed a methodology for the assessment of exposure of soil organisms to pesticides, because harmonised European procedures are currently not available. Based on ecotoxicological considerations, this methodology was developed both for the concentration in total soil and for the concentration in soil pore water. The goal of the exposure assessment has been chosen to be the 90th percentile of the exposure concentration (maximum over time) in the intended area of use in the three regulatory zones defined in the Pesticides Regulation. The endpoint of the exposure assessment is a spatio-temporal percentile of a concentration distribution, so this distribution had to be modelled first. This was done with a simple analytical model, because data to parameterise detailed numerical models are not available at the scale of the EU-27. From the so-obtained concentration distribution, 90th percentile scenarios were selected. Separate scenarios were developed for the concentration in total soil and for the concentration in pore water giving six scenarios to be developed. The scenarios were defined by their air temperature, soil organic matter content and soil textural class. For each of these scenario's, the numerical models PEARL and PELMO were parameterised. (These models are already routinely used for the assessing the potential for movement of pesticides to groundwater.) The concentration in total soil decreased in the order North>Central>South, whereas the concentration in the pore water showed an opposing trend with the highest concentration in the Southern European scenario. This is caused by the North-South trend of organic matter in the EU.

PESTICIDE INTERACTIONS IN SOILS, SEDIMENTS AND WATER

Harrison Rebecca^{*[1]}, Michaelides Katerina^[1], Freer Jim^[1], Bull Ian^[2], Hurley Steven^[3]

^[1]Bristol University ~ Geographical Science ~ Bristol ~ United Kingdom ^[2]Bristol University ~ Organic Geochemistry Unit, Department of Chemistry ~ Bristol ~ United Kingdom ^[3]Wessex Water Ltd ~ Operations ~ Bath ~ United Kingdom

Transport of pesticides in runoff and subsurface flow during rainfall events poses a significant concern for water quality with adverse effects on drinking water and aquatic life which may lead to serious and long-lasting ecotoxicological effects. Pesticide transport from fields to water courses has been shown to be accentuated by erosion of sediment-bound pesticides which can be a significant component of surface-water contamination and off-site pollution. Laboratory soil lysimeter experiments (0.03 m³) were used to monitor the vertical, flow-driven movement of different pesticide compounds over successive storm events. Known concentrations of commonly used pesticides were applied to dried and pre-wetted soil and subjected to rainfall simulations over a 2-week period. Leachate was collected at regular intervals during each rainfall simulation and analysed for pesticide concentrations. Cored soil samples from the lysimeters were analysed after each experiment in order to determine the concentration profile of sediment-bound pesticides and the relative partitioning between the dissolved and sediment-bound phases. Pesticides with different properties (half-life, degradation products, toxicity, soil-water partition coefficient) were used in order to determine differences in transport characteristics according to compound classes. The experimental results are used to constrain catchment sampling design for determining large-scale transport and residence times of pesticides in the context of drinking-water management.

INTERACTIONS OF HERBICIDES WITH ORGANIC MATTER AND DISSIPATION PROCESSES

Burauel Peter*^[1], Nicolai Jablonowski^[1]

^[1]Forschungszentrum Juelich GmbH ~ Agrosphere Institute, IBG 3 ~ Juelich ~ Germany

There are almost no sites worldwide which are not affected in various manner by the use of agrochemicals. In terrestrial systems, soils function as the major sorbent and sink for locally and widely applied pesticides. This function critically depends on the quantity and quality of soil organic matter, the microbial activity and diversity, and the amount and accessibility of biogeochemical interfaces in soil. Soils are highly heterogeneous, complex and sensitive to changing environmental conditions and land use systems. In this respect the deterioration of soils by an increasing loss of soil organic matter is a challenge. Almost half of European soils can already be assessed as being degraded with unknown effects in matter cycling (nutrients, pesticides, contaminants). This will be fostered by an increased demand of farmland used for biomass/bioenergy production. Soils can also function to offset CO₂ emissions from fossil fuel combustion by introducing soil and crop management practices which enhance the input of biomass carbon into the soil – another challenge in matter cycling. A changing carbon status of our soils will effect persistence, bioaccumulation, bioaccessibility, and toxicity of pesticides. The behaviour of binding and remobilization of aged pesticide molecules in soil and their microbial remobilization potential will be highlighted in this presentation. Results will as well tackle the potential remobilization of aged pesticide residues by an intense sequence of drying and wetting cycles which simulate drastic soil water potential changes increasingly occurring due to regional effects of climate change.

ROLE OF CLAY AND ORGANIC MATTER IN AN AGRICULTURAL SOIL ON THE FATE OF THE HERBICIDE SULCOTRIONE

Dumas Edith^[1], Alekseeva Tatiana^[2], Sancelme Martine^[1], Forano Claude^[1], Besse-Hoggan Pascale^{*[1]}

^[1]Institut de Chimie de Clermont-Ferrand - CNRS ~ Université Blaise Pascal ~ Aubière Cedex ~ France ^[2]Institute of Physical, Chemical and Biological Problems of Soil Science ~ Russian Academy of Sciences ~ Pushchino ~ Russian Federation

Dissemination of pesticides in agricultural soils occurs via interactions with solid particles and microorganisms. These interactions play a key role in their biodegradation by acting not only on their bioavailability but also on the microbial metabolic activity. In order to better understand the mechanisms involved in the transfer/transformation processes of pesticides and to identify the role of each soil component on their fate, we developed a multi-scale experimental study. Agricultural soil samples (Limagne plain, France), particularly rich in clay and organic matter, were separated into three fractions : 50 μ m -500 μ m; 2 μ m- 50 μ m; < 2 μ m. A particular focus is put on the fine fraction, containing mainly clay minerals, known to determine most of the physicochemical properties of the raw soils and to have a major effect on the adsorption of xenobiotics. A triketone herbicide, sulcotrione, used as a selective herbicide in maize, was chosen. Adsorption isotherms and kinetics of the various soil fractions were determined to quantify the soil response to pesticide contamination. The effect of organic matter on sulcotrione immobilization was studied by comparison of clay fractions and organo-clay fractions. Biodegradation is another important process controlling the fate of pesticides. Using a soil-mineral medium containing the herbicide, sulcotrione-degrading microorganisms were isolated. Among four bacterial colonies, one strain showed high capacities of biotransformation. A detailed study of the biodegradative pathway was carried out to identify the metabolites formed. The metabolism in water and in the presence of bulk or soil fractions was compared in terms of kinetics and pathways.

With the coming into forces of the European directive 2009/128/EC the sustainable use of pesticides becomes a duty for all the European Member States. The directive establishes a framework to achieve sustainable use of pesticides by reducing them risks and impacts on both human health and environment. Many studies report the good capacity of organic substrates on retaining or/and degrading pesticides but a high influence of substrates characteristics and the adsorption/degradation conditions (aerobic/anaerobic) was observed. The present study aims at testing the capacity of a biomix on retaining pesticides from a mixture solution in oxygen - limited conditions. The oxygen-limited conditions of working of the biological plant were mainly chosen for practicability and safety system reasons. The system is composed by two cylindrical plastic containers. The first one, where the pesticides solution is collected, is open, whereas the second one, where the biomix is disposed, is closed. The pesticides solution was pumped at the biomix surface and subsequently recollected and disposed in the first container, for 15 days. Four pesticides with different physic-chemical characteristics and in two environmental temperature conditions were tested. The results obtained after the first retention test revealed a relatively good retention capacity of the biomix for the pesticides tested, but repeating the experiment, in some cases, was observed even an increase of pesticides concentration into the water ,which could be due to desorption of previously adsorbed quantities. Therefore, the developed water treatment plant doesn't show the expected efficiency and further modifications are required.

Biodegradation of pesticides in soil is actually understood as their transformation into various metabolites, microbial biomass, mineralisation products and non-extractable residues (NER). NER are believed to mainly consist of hazardous parent compounds or primary metabolites sorbed to or sequestered by soil organic matter (SOM). Up to date, however, their chemical composition remains still unclear. This is because numerous studies on NER formation are limited to quantitative analyses in soils or to simple humic acids-contaminant systems. During biodegradation of organic contaminants, the C is used by microorganisms for their biomass synthesis. After the cell lysis, biomass components are stabilised in the SOM forming ultimately harmless biogenic residues. We compared the transformation of isotope labelled model pesticides (2,4-D, atrazine) into the NER in the biotic and abiotic soil experiments. In both setups we quantified the contribution of microbial biomass to NER formation. We prove for the first time that nearly all NER formed from readily biodegradable pesticides in soil derived from non-hazardous microbial biomass components. In contrast, in the abiotic set-up, the total NER contents were much lower than those in the biotic set-up. The absence of labelled biogenic components in the NER fraction in abiotic soils thus demonstrated that they contained exclusively potentially hazardous parent compound and / or their metabolites. Therefore, for the proper assessment of the potential risks of a target contaminant in soil to human and environment it is necessary to consider a possible biogenic origin of NER in the mass balances of contaminants in soils.

NANO-PESTICIDES: STATE OF KNOWLEDGE, FATE AND EXPOSURE ASSESSMENT

Kah Melanie^{*[1]}, Beulke Sabine^[5], Tiede Karen^[5], Hofmann Thilo^[1]

^[1]University of Vienna ~ Environmental Geosciences ~ Vienna ~ Austria ^[2]Sand Hutton ~ Food and Environment Research Agency ~ York ~ United Kingdom ^[3]Food and Environment Research Agency ~ n/a ~ York ~ United Kingdom ^[4]Food and Environment Research Agency ~ Sand Hutton ~ York ~ United Kingdom ^[5]Food and Environment Research Agency ~ Sand Hutton ~ York ~ United Kingdom

Nano-formulations are already used in the pharmaceutical and food industries. In comparison, applications in the agrochemical sector are only emerging and a rapid growth is predicted in the upcoming years. Deliberate application of nanoparticles as within agricultural practices could be one of the rare intentional diffuse inputs of engineered nanoparticles into the environment. It is thus essential that risks and benefits to human and environmental health are adequately evaluated. Nano-pesticides encompass a great variety of products and cannot be considered as a single category. Many nano-formulations combine several surfactants, polymers, and metal nanoparticles in the nm size range. The aims of nano-formulations are generally common to other pesticide formulations and consist in increasing the apparent solubility of poorly soluble active ingredient (a.i.), releasing the a.i. in a slow/targeted manner and/or protecting against premature degradation. Nano-formulations are thus expected (i) to have significant impacts on the fate of a.i. and/or (ii) to introduce new ingredients whose environmental fate is still poorly understood (e.g. nano-silver). Therefore, it seems that adaptations of current exposure assessment approaches will be necessary, at least for some nano-pesticides. The aim of the present study is to (i) review the current state of knowledge on nano-pesticides, (ii) identify possible impacts on environmental fate and (iii) analyse the suitability of current pesticide exposure assessment procedures to account for novel properties. A variety of sources were extensively searched and relevant information was combined from published literature, company websites, patent databases, reports from governmental and non-governmental institutions.

PolyChlorinated Byphenyls (PCBs) are among the most widely spread and persistent organic pollutants. Given their hydrophobicity and low vapor pressure, PCBs accumulate in the soil organic fraction. In spite of this affinity, a portion of the soil PCBs is released into the atmosphere due to seasonal soil temperature variations. Soil temperature is also influenced by terrain features, which can account for differences in the soil PCBs reservoir. Thus the assessment of PCBs contamination requires a reliable spatial and temporal mapping for flux assessment. This is particularly critical, as the mobilization of PCBs increases their transfer to the food chain through capture by vegetation. In this work, we propose a general framework for the prediction and mapping of soil PCBs contamination based on soil organic carbon content and terrain features. This includes the setup of physical algorithms to derive the spatial and seasonal distribution of the contamination potential for PCBs in the soil. The developed maps were validated with an external set of CB-153 contamination data, showing good performance ($R^2 = 0.80$, $p\text{-value} = 2.2 \cdot 10^{-06}$). The model was used for the mapping of the actual soil contamination, taking into account the temporal shifts in concentrations from the equilibrium (as defined by K_{sa} values). A consequent dynamic model of seasonal variation of the soil concentrations was able to describe the observed concentrations asymmetries between the discharge and the recharge stage, explaining the observed low autumn PCB concentrations in relation to the high K_{sa} values of this period.

In conservation agriculture, pesticide interception by plant residues used as mulch is major process affecting their degradation and further mobility. The efficiency in the reduction of losses may highly depend on mulch decomposition in relation to climatic conditions. We studied the transformations of S-metolachlor under two different rainfall regimes in soil columns covered with mulch of Zea mais + Doliquos lablab. Rain1 (temperate, twice a week) with week intensity (6 mm/hr) and Rain2 (tropical, twice a month) with stronger intensity (20 mm/hr) were chosen as treatments resulting in the same amount of rainwater received per month (20 mm). Columns were incubated at 20 °C for 85 days to monitor soil water, C, N and pesticide dynamics. Destructive sampling allowed to analyse herbicide residues in mulch and soil at three depths after 0, 14, 41 and 85 days. Soil solutions were sampled at the same depths through porous suction cups 8 hours after rainfall every fifteen days. Results showed that 55-60% of applied herbicide was intercepted by mulch residues whereas 35% was found in the 0-5 cm soil layer. Rainfall regime strongly influenced the dissipation of S-metolachlor in mulch and soils. S-metolachlor was transported to deeper soil horizons under the tropical regime. A greater mobility was observed for the more soluble and less sorbed metabolites OA and ESA. By contrast, s-metolachlor remained mainly in surface layer and was more rapidly degraded in the mulch under temperate rainfall regime. Water, mulch C transformations and S-metolachlor dynamics were simulated with the PASTIS model.

^[1]Laboratoire Microorganismes : Génome et Environnement ~ Biology ~ Aubière ~ France ^[2]Laboratoire de Synthèse et Etude de Systèmes à Intérêt Biologique ~ Chemistry ~ Aubière ~ France

In a context of production system sustainability, new generation molecules, more specific in their targets, are applied at "low doses" and as "mixtures". However, these new agricultural practices are rarely taken into account in assessing eco-toxicological profiles of pesticides. The "cocktail effect" approach is essential to link cumulative, synergistic or antagonistic effects of pesticide mixtures and to permit a better comprehension of environmental consequences of multiple applications. In this approach, we assessed the impact of maize herbicide "cocktails" on microbial communities. Callisto® (Mesotrione) and DualGold® (S-metolachlor) were applied at recommended and ten-fold field rates on soil microcosms. Our results emphasized a synergistic effect in "cocktail" treated microcosms with (1) an increase of the Mesotrione herbicide dissipation time and (2) an effect on the bacterial, fungal and phototrophic communities which were at least equally impacted by the field rate mixture application compared to the ten-fold field rate application of molecules used separately. Moreover, variations observed for the nitrogen could also be explained by impacts on the communities involved in its mineralization. In order to confirm our previous hypothesis and to pursue the investigation, the Nicosulfuron herbicide (Milagro®) was added to the mixture. We focused our work on structural and functional proxies of the total communities (bacteria and fungi) involved in the mineralization of organic matter and on phototrophics, nitrifiers and denitrifiers groups. By linking chemical and biological data, our experiments will contribute to develop tools that assess the soil health, for a reasoned choice of pesticides use.

The presence of herbicides used in olive orchards at Guadalquivir river basin is a severe problem and hence, the study of the soil processes affecting those herbicides is important to design strategy to minimize that adverse effect. The objective of this work was to assess the soil processes affecting the herbicide oxyfluorfen (2-chloro-4-trifluoromethylphenyl-3-ethoxy-4-nitrophenyl ether) and the effect of olive oil mill waste (OMW) amendment in two soils (P2 and SJ) of South. The relationships of relevant oxyfluorfen soil processes and its concentrations measured in surface and ground water is attempted. Sorption-desorption studies showed higher oxyfluorfen sorption upon amendment, presumably due to the higher OM. DT50 values for SJ (29d) and P2 (19d) increased with moisture, whereas OMW amendment with increased much longer. Leaching potential of oxyfluorfen was very low, decreased with temperature and increased upon amendment. This mobility is related to soil porosity distribution and their changes with amendment enhancing the vertical movement. Dissolved organic matter (DOM) it could have also a role. The low deep mobility at 4°C, as compared to 25°C, it could be related with the maximum oxyfluorfen concentration in surface water measured at December (4-12°C), whereas those of ground water were measured at April-May (17-25°C).

Pharmaceuticals used in large quantities throughout Palestine as prescription and non-prescription drugs have been reaching the environment via different routes. Hence, a new technology is needed for the removal of such pharmaceuticals from wastewater. In the study to be presented, the efficiency of the components of an integrated system containing hollow fiber, spiral wound (UF membranes), carbon, clay micelle complex filters and RO membranes towards the removal of several NSAID drugs were investigated. Kinetic studies on the removal of several NSAIDs drugs and their degradation products were studied in pure water and wastewater conditions. Adsorption of studied compounds onto a clay- (octadecyltrimethylammonium) micelle complex and activated charcoal adsorbents were investigated. Equilibrium relationships between adsorbents (i.e. clay micelle complex and activated charcoal) and adsorbate (i.e. NSAID drug) were described by Langmuir adsorption isotherms. A list of the Langmuir constants, k , and the values of maximum mass of pharmaceutical removed per gram of adsorbent, Q_{max} , is reported. Aspirin and Paracetamol were easily degraded in water or sludge giving rise to salicylic acid and p-aminophenol, respectively, and a stoichiometric amount of acetic acid. Naproxen resulted in desmethylnaproxen as main byproduct in sludge. Diclofenac, ibuprofen and mefenamic acid were not degraded during the observation time.

KEEPING OF INFORMATION ABOUT ENVIRONMENT OF ANCIENT MAN HABITAT IN PALEOSOLS OF DIFFERENT BURIAL CONDITIONS

Dergacheva Maria*^[1], Gavrilov Denis^[1]

^[1]Institute of Soil Science and Agrochemistry SB RAS ~ Laboratory of biogeocenology ~ Novosibirsk ~ Russian Federation

The problem of information keeping about past environment in paleosols is very actual in archaeological pedology. There are no enough materials experimentally proving the degree of pedogenic feature preservation in time. Preservation and changeability of pedogenic features under different conditions of paleosol and deposit burials on the Nura – Ishim interfluvium (Northern Kazakhstan) were studied. The territory is typical for dry steppe and has a number of archaeological objects with paleosols buried in different Holocene periods under barrows, banks and old buildings ruins. A chronosequence of paleosols (1200-1100 yrs, 1000-800 and 700-600 yrs) buried under same genesis deposits (settlement Bozok), underbarrow paleosols of the same age overlapped with the deposits of sharply different genesis (burial ground Kuigenzhar) and of different age and paleosols buried under stone barrows (burial ground Tegiszhol) was considered. All compared objects are located in a short distance. Study of paleosol morphological, physico-chemical characteristics, humus composition and humic acids revealed that their preservation depends on the composition of the overlapped depth. Paleosols buried with the material close to them in genesis and features have well preserved main characteristics and man habitat reconstruction coincides with that of other paleogeographical methods. When a barrow was made of the ground with genesis differing from that of burial ground site, i.e. under sharp change of paleosol functioning conditions after burring, paleosol mineral part changed greatly and morphological and physico-chemical pedogenic features vanished. And information about paleoecological conditions of ancient man habitat in the changed environment is best kept in humic acids composition.

The preceramic and continental peopling issues at Veracruz has been abandoned almost completely. Only two projects on this concern have been developed, one between the last century 60's and 80's by Jeffrey Wilkerson (1973- 1987) and the other one is the present research: that begins at 2009. We have done three intensive excavation units, where we found several lithic artifacts, in order to understand how people utilized various resources across the landscape and through time. Another important question is how the environmental conditions were in this site during the occupation period. To solve the latest we have done a soil profile, identifying the buried paleosols in relation to the presence of artifacts. Samples from each paleosol horizon have been taken. Then we have analyzed texture, stable isotope composition, organic matter content, magnetic susceptibility and micromorphology, properties that integrate the soil memory. The stratigraphy between the three archaeological units is similar however in one of the sections we recognized the presence of a buried paleosol. This paleosol has a well differentiated Ah horizon (dark color, granular to subangular blocky structure), a thin E horizon (paler than Ah, more silty), a Bt (brownish, clayey, with subangular blocky structure) and C horizon (weathered gravels of alluvial origin). This well developed soil overlies the artifacts, thus it represents the conditions after the first settlement, giving, additionally a good material to establish the chronological frame.

Modern archaeological studies are becoming increasingly multi-disciplinary by drawing on the expertise of the natural sciences, including soil science. The contribution of soil science is pivotal in the study of ancient land use systems, where opportunities for archaeological dating are often limited. New prospects for their chronological attribution are offered by the method of soil-genetic chronology (SGC), which is based on the mathematical dependency of irreversible genetic soil properties on time. Both the morphological and functional properties of the newly formed soils prove to be chronologically indicative. The SGC method has been effectively applied in the study of the Early-Iron-Age archaeological sites and features on the Tarkhankut Peninsula, Crimea (e.g. Panskoe, Ak-Mechet and Jarylgach 2). Soils were studied in trenches, revealing the entirety of recent horizons accumulated since the end of habitation for residential areas or the last addition for earthen structures. The study of a land division system identified near Cape Tarkhankut and the regional calibration of the model allowed the end of its use to be assigned to the early 3rd century BC. This conforms to the date suggested by pottery from individual land plots and associated farmsteads identified there. To enhance its reliability, the dating by the thickness of the humus horizon of newly formed soil must be supported by the data on soil properties such as the supply of organic material and its 'maturity', the extent of leaching carbonate and/or their distribution across the soil profile, and the development of soil structure.

We investigated a pedo-sedimentary sequence (Bosquet) located in the Pla de Les Alcusses, an area that was occupied at least since Neolithic times and probably intensely cultivated during the Iberian period (5th-4th centuries BC). The sequence, developed on marls, was sampled at high-resolution. Analyses included physico-chemical properties, mineralogy, elemental composition (XRF), infrared spectroscopy (FTIR), molecular composition of the organic matter (pyrolysis GC-MS), and radiocarbon age dating. Six cycles were identified. A significant increase in carbonate leaching and enrichment in low-mobility elements (like Al, Fe and Ti) was found from cycles VI to V, pointing to humid, and possibly warm, conditions in the mid Holocene. A sharp increase in carbonate content at the base of cycle IV -which remains almost constant until the top of the sequence- reflects a change to much drier conditions after ca. 5580-5300 cal BP. The molecular composition of soil organic matter showed a simultaneous shift from microbial-derived SOM in cycles VI-V towards predominantly plant-derived SOM, suggestive of a strong difference in SOM dynamics accompanying aridification. Cycle IV contained abundant pottery fragments at its top and may represent the cultivated Iberian age soil. Cycle III showed Pb enrichment at its surface, pointing to significant mining and metallurgical activities in Roman times. Cycle II is a modern agricultural soil with evidence of management and application of pesticides. While cycle I represents the present cultivated surface. Acknowledgements. Financial support for this research was provided by the Diputación of Valencia, ERC project AGRIWESTMED and project HAR2008/08435 of Spanish MICINN.

In this study multi-element soil analysis is applied to Çatal Oluk, a Classical-Hellenistic to Roman-Late Roman archaeological site located in the suburban zone of ancient Sagalassos (Taurus Mountains, SW-Turkey). The aim of the research is to evaluate to what extent geochemical analysis of the soils at this site can help delineate local activity areas. Çatal Oluk has not yet been excavated, but geophysical research has revealed the presence of buried kilns, which show a spatial association with large concentrations of ceramic tiles and pottery that were collected during archaeological surveying campaigns. A total of 150 topsoil samples have been gathered in a regular grid, together with 40 soil samples taken in 3 drill cores with depths between 0.7 and 2.5m. Aqua Regia extractions were conducted on the fine fraction (<63 µm) and the elements Al, As, Ba, Ca, Cu, Co, Cr, Fe, K, Mn, Mg, Na, Ni, Pb, P, Si, Sr, Ti, V and Zn were measured using inductively coupled plasma optical emission spectrometry (ICP-OES). Spatial and statistical data analysis revealed a geochemical anomaly of Co, Cr, Ni and Mg at and around the buried kilns. This could reflect the remnant signatures of ophiolitic clays that were transported to the kilns, to be used as a raw material for the production of ceramics. As Çatal Oluk is situated on a colluvial plain, the presence of colluvial material in the soil, including fragments of ophiolitic material, has to be taken into account in the interpretation of the geochemical data.

Soils have a capacity to store information, referred to as 'soil memory'. Hence, they herald our natural and cultural heritage: soils provide insights into their development under past environmental conditions and into past (agri)cultural practices. This information may be so relevant that soil can be considered to all effects and purposes - including legal – having “cultural and/or natural heritage”. During recent decades however, the area of undistrubed soils in Europe decreased at a dramatic rate. An important cause for this degeneration and loss is the lack of knowledge and methods to recognise and validate remarkable soil bodies. Therefore, a framework to recognise, evaluate and manage soils of natural and cultural heritage value is necessary for conserving and validating these soils in Europe. Despite an increasing number of soil scientists who are actively working on the topic, widespread co-ordinated work in Europe is still lacking. An international effort is vital to identify and evaluate European soil bodies of national and international importance, to harmonize definitions and criteria, to explore the scientific, educational and touristic potential and to develop the incentive necessary to propose a conservation strategy. In order to achieve such a joint European effort, the ECHo-Soil incentive is proposed: “European Cultural Heritage of Soil”. This incentive aims at providing a forum for discussion for scientists working in the field of soil heritage, hereby providing a framework for idea’s and impact evaluation, an aid in soil heritage science and education and a starting point for raising awareness.

UNLOCKING THE HIDDEN LEGACY OF HUMAN SOIL INHUMATION: MICROMORPHOLOGY OF ST. ROMBOUTS GRAVEYARD, MECHELEN.

Lang Carol^[1], Wilson Clare^[2], Brothwell Don^[1], Usai Maria-raimonda^[1]

^[1]University of York ~ Archaeology ~ York ~ United Kingdom ^[2]University of Stirling ~ School of Biological and Environmental Science ~ Stirling ~ United Kingdom

This paper focuses on a case study within a larger multi-disciplinary ERC-funded research project, InterArChive. One hypothesis of the project is that archaeological, historical and burial information can be retrieved from grave soils/sediments by integrating a micromorphological approach with chemical investigations. St Rombouts Cathedral's graveyard, on the River Dijl, Mechelen, Belgium was instrumental in preliminarily testing aspects of the InterArChive methodology. The graveyard and burials were the results of complex multi-period utilisation (13th to 19th centuries), thus an ideal site to test the hypothesis. A systematic sampling protocol was followed, and micromorphological and elemental SEM investigations and image analysis were carried out. Significant uniformity of elemental composition, soil texture and mineralogy were observed, with rubified clay and glauconite present throughout all graves and site controls. In contrast, pedality of the soil from the skull region was significantly different to that of most other samples. This suggested that investigation on soil aggregation in relation to regional body decay should be extended to a wider selection of sites/soils. Dirty coatings were also in preferential positions near the skull, and lined bone voids and surfaces. This prompted the question on whether such accumulations might have helped in the preservation of the bone. The presence of excremental pedofeatures indicated post burial bioturbation, whilst parallel referred distribution of channels and micro-structure suggested post-burial anthropogenic influence and compaction. Concentrations of Ca and Fe were higher in the foot region. This work induces wider debate surrounding the preservation, degradation, and subsequent dispersal of burial products.

IN SITU PRESERVATION AND PRESENTATION OF HERITAGE SOILS IN LANDSCHAP DE LIEREMAN (BELGIUM)

Van Der Veken Bas^[1], Bastiaens Jan^[2], Van Gils Marijn^[2], Huyghe Natalie^[2], Oomen Evelien^[2], Vancampenhout Karen^[3]

^[1]Regionaal Landschap Kleine en Grote Nete ~ - ~ Kasterlee ~ Belgium ^[2]Flanders Heritage Agency ~ - ~ Brussels ~ Belgium ^[3]Affiliation KULeuven / KHKempen ~ Earth and Environmental Sciences ~ Leuven ~ Belgium

Landschap De Liereman is a 1000 ha landscape and important nature reserve in the Campine area in northern Belgium. It has a high heritage value, including Palaeolithic and Mesolithic archaeological sites. Landschap De Liereman is characterized by a north-south topographical gradient with dry sand dunes and wet marshes and a west-east anthropogenic gradient from agricultural land to undisturbed natural soils. As such, it is a pattern-card of soils typical for the region and a living memory of landscape evolution and former land-use. Therefore preservation and presentation of 'geo-diversity', as opposed to 'bio-diversity', was included as a main goal in the management plan. Some principles regarding the conservation of soils were adopted, every action to improve bio-diversity is weighed to preservation of geo-diversity and soil research is stimulated. Moreover, presenting soil heritage to the public is quite a challenge, given the complexity of soil profiles and the instability of classical profile pits. New ideas were evaluated, and the first steps have been taken in the development of an educational soil trail together with a prototype of a new method for in situ presentation, showing both the in situ soil profile and archaeological findings along with educational information. The location chosen for the prototype is a heathland setting with a podzol (with Mesolithic artefacts) over an Usselo-soil (with late-Palaeolithic artefacts). The educational soil trail is intended to use in situ soil profiles as means to explain the local pedology, geomorphology, past and present vegetation, archaeology and human land-use to the general public.

The main objective of our research was evaluate the potencial of colluvial soils from an archaeological site to reconstruct Holocene environmental changes. We aimed to understand the link between human activity and the wider environmental context. To developed the research we sampled at high resolution a thick (150 cm), black, organic matter rich, colluvial soil. Analyses included: sedimentary features, elemental composition and physico-chemical properties of the inorganic phase, an pedoanthracological study and radiocarbon age dating. We identified two stratigraphic units: the basal one was represented by a paleosol formed between 7670-7580 cal. BP and 4090-3920 cal BP. This unit is rich in gravels, sands and charcoal, and showed significant vertical variations in the elemental composition of the inorganic phase (Ti, Zr, Fe, Al). The younger unit began to accumulate after 4090-3920 cal BP and it is a sandy, highly organic, and more acidic colluvial soil. Charcoal analyses suggested a landscape dominated by forest in the lower unit and a sharp change to shrub vegetation in the upper unit, to the point that the charcoal of the bottom samples (the highest content in the sequence) of the upper unit are exclusively composed of Fabaceae. This points to a dramatic regression of the forest after ~4000 cal BP promoted by human-induced fires, leading to shrubland expansion, landscape instability, and increased soil erosion and acidification. Acknowledgements. Manuela Costa-Casais is supported by a Research Program "Isidro Parga Pondal 2007" - Xunta Galicia. This research was partially funded by the Project 09SEC015606PR (2009-2012).

CHARCOAL-AFFECTED SOILS AT MOUND KILN SITES IN WALLONIA, BELGIUM: FROM HISTORICAL LAND USE TO SOIL HERITAGE

Hardy Brieuc*^[1], Cornelis Jean-Thomas^[1], Dufey Joseph E.^[1]

^[1]Université Catholique de Louvain ~ Earth and Life Institute - Environment ~ Louvain-la-Neuve ~ Belgium

From the 16th to the early 20th century, iron metallurgy was the biggest economic activity in Wallonia, Belgium; more than 75 metallurgic operations of varying size have been listed during this time period. Ancient forge and stove locations mainly depended on the proximity of three key resources: iron ore; rivers ; and forests to supply charcoal, the unique combustible used for heating and reducing iron until the late 19th century. Charcoal was produced in the forest by the “mound kiln” method: after removing the soil organic layers, wood was accumulated in a circular mound and isolated from oxygen with a covering of soil and vegetation residues. A fire was set within a central chimney, and the thermal action exerted by warm gases passing through the mound induced wood charring by pyrolysis. Soil has been highly disturbed at mound kiln sites where charcoal residues, given their stability within the soil, are still present in large quantities. These residues affect physical, chemical and biological soil properties, as well as pedogenic processes. Mound kiln sites can be identified in ploughed fields as dark circular or elliptical areas 25 to 40 m in diameter, and on forest floors as heightened domes with diameters of 6 to 15 m. Here we focus on : (1) the spatial and temporal occurrence of charcoal production by mound kiln; (2) the technical aspects of this charring method; (3) the approach we use to inventory mound kiln sites at regional scale using aerial photographs, historical documents and ancient maps.

^[6]Università di Firenze ~ Department of Evolutionary Biology ~ Firenze ~ Italy

Since the Etruscan Iron Age (8th–6th centuries BC), southern Tuscany (Italy) has been characterized by intensive mining and smelting activity, resulting in a significant release of arsenic to the environment. In a previous work, Harrison et al. (2010) hypothesized that industrial pollution and arsenic poisoning might actually have stimulated, among other related events, social crises in Etruscan civilisation and the peaceful abandonment of several important settlements which occurred, during and at the end of the Archaic period, in sites such as Lago dell'Accesa, Acquarossa and Poggio Civitate-Murlo. However, the X-ray fluorescence analysis of a hair sample from a Faliscan woman (c. 350 BC), did not allow a thoroughly satisfactory demonstration of this hypothesis, most probably because women buried in chamber tombs were not exposed to high levels of arsenic in life, or arsenic concentration in the tested hairs did not exceed the instrumental detection limit. Rasmussen et al. (2009) found a very high concentration of arsenic in Danish and Swedish Mesolithic and Neolithic human bones and discussed the origin of this contamination. In the present study, we analysed the arsenic concentration of bones, soil and other environmental samples from Lago dell'Accesa site, to discuss further the phenomenon of toxic exposure among ancient Etruscans and to exclude bone diagenesis as a possible source of arsenic in human remains. We used both ED(P)-XRF and ICP- (OES and MS) technique, since the former is less sensitive but allows for non-destructive testing, whereas the latter is much more sensitive but necessitates destructive testing.

SOILS FOR SUSTAINABLE DEVELOPMENT

Klaus Lorenz^{*[1]}, Jes Weigelt^[1], Rattan Lal^[2], Thando Tilmann^[1], Klaus Töpfer^[1]

^[1]IASS Institute for Advanced Sustainability Studies Potsdam ~ Global Contract for Sustainability ~ Potsdam ~ Germany

^[2]The Ohio State University ~ School of Environment and Natural Resources ~ Columbus, OH ~ United States

Soil is a finite global resource. Fertile soils form the basis needed to sustain the demands of an ever increasing human population for food and play also a pivotal role in global material cycles. However, soil quality is declining due to a wide range of degradation processes (i.e., erosion and the depletion of soil organic matter and plant nutrients). Existing policy instruments, charters and resolutions have not been sufficient to restore, improve, sustain and enhance global soil resources. Thus, more coordinated efforts are needed to sustainably manage soils to address the important global issues of the 21st century, like food security and climate change mitigation. The paper reviews analyses of international environmental policy initiatives to infer lessons that could inform global soil policy processes. These analyses converge in emphasizing the importance of the following elements: (i) international organizations as actors in the process, (ii) independent scientific advisory bodies and, (iii) multilaterally accepted institutional design that unites ecological and economic concerns of the parties under the umbrella of sustainable development. Based on these elements, the paper analyses current international policy efforts towards sustainable soil management. It is emphasized that current global initiatives such as the Global Soil Partnership initiated under the auspices of FAO are starting to implement the necessary elements identified above. However, concerted efforts by a range of actors are needed to cope with the challenges posed by soil degradation. In conclusion, the paper outlines possible steps towards global sustainable management of the finite resource soil.

SOIL, PARTNER IN SUSTAINABLE DEVELOPMENT: IMPORTANCE OF AN ACTIVE SCIENCE POLICY INTERFACE

Boekhold Sandra^{*[1]}, De Cleen Margot^[2], Otte Piet^[3]

^[1]Soil Protection Technical Committee ~ secretariat ~ The Hague ~ Netherlands ^[2]Ministry of Infrastructure and the Environment ~ Space and water ~ The Hague ~ Netherlands ^[3]National Institute for Public Health and the Environment ~ ecology lab ~ Bilthoven ~ Netherlands

Climate change, energy shortages, urbanization, health and food security are societal and economic challenges for the coming decades. Soil, together with seas, oceans and lakes determines interregional climate effects, water balance, food production and conditions for biodiversity and human health. Therefore, soils are part of the answer to meet these major challenges imposed to man. We believe that advocating this perspective may contribute to raising awareness on the importance of soil for society. In 2009 a contract was signed with the competent national, regional and local authorities in which they support a transition from a soil policy developed for protection goals only towards an integral policy based on sustainable use of soil (including protection). The design of a national agenda on strategic knowledge needs and the development of an innovative research program was part of this contract. Knowledge gaps were identified, analysed and discussed. The physical environment acts on scales in time and space which may differ with interventions and their effects. The response time for soil related interventions is usually slow. Understanding of the functioning of the soil, the ecosystem services and the interrelations of the different soil functions, is essential for planning and defining the right policy measures. The agenda also contains proposals for an efficient organisation and planning of soil research. We will present the process of consensus building between the authorities and other stakeholders and its result. We will elaborate on the importance of an active science policy interface.

LAND-USERS EDUCATION IN SOIL AND SOIL QUALITY FOR SUSTAINABLE FARMING IN A COMMUNITY-BASED PARTICIPATORY RESEARCH PROJECT IN ORDUÑA (BASQUE COUNTRY, SPAIN)

Imaz Maria José^{*[1]}, Virto Iñigo^[1], Enrique Alberto^[1], Bescansa Paloma^[1]

^[1]Universidad Pública de Navarra ~ Ciencias del Medio Natural ~ Pamplona ~ Spain

Although traditional knowledge on soil and soil quality has been wide among farmers and rural population, reality in many areas of Western countries is that many land users ignore or have confusing information on the soil they use for crops or cattle production. This is so because, in many cases, traditional knowledge has been replaced by commercial or market-oriented advice without enough attention paid to the site-dependent characteristics of the soil resources. In this work, we present the results of a community-based participatory research project in Orduña (Basque Country) in the framework of Agroecology, in which education on soils and soil quality, and the recuperation of knowledge on local soils and traditional land management have been the basis for a successful local development program. The program started in 2007 with the support of the local administration. It involved the local farmers association, local extensionists, and soil scientists from the Universidad Publica de Navarra. Seminars and workshops on soil and soil quality were among the various activities undergone during this program. Four years later, this program has resulted in the creation of a group of promoter farmers which designs alternatives for the improvement of their own farms at the beginning of each production season. These alternatives are followed-up and evaluated by the entire community. As a result, previous management techniques have been replaced by more sustainable land use systems, based in soil quality conservation principles, in more than 200 ha.

RAISING AWARENESS: SOIL SCIENCE'S GREATEST CHALLENGE?

Montanarella Luca^[1], Jones Arwyn^{*[1]}, Panagos Panos^[1], Gardi Ciro^[1]

^[1]European Commission ~ Joint Research Centre ~ Ispra ~ Italy

Communicating the value and importance of soil is arguably one of the greatest challenges facing the soil science community today. Active protection and sustainable use of soil can only be achieved through a societal understanding of its role and the value, from an economic, ecological and community perspective. Increasingly, soil scientists have begun to realize the importance of the need to communicate these issues to the wider world. However, these efforts are often local and temporal. This presentation discusses the possibilities to address society as a whole and bring about a sea-change in public perception of soil through actions and measures at both pan-European level and within individual Member States.

S13.02 -5

SOILS AND SOCIETY: FRAMEWORKS AND APPROACHES – A STOCKTAKING EXERCISE

Hartmann Ingrid*^[1]

^[1]Desertnet International ~ Soil Science ~ Berlin ~ Germany

Hans Jenny perceived the status of soils as a function of climate, relief, paternal material and anthropogenic influences. Conventional soil science has focused particularly on the former factors and therefore remained almost a biophysical science until now. Nobelist Paul Crutzen on the other had has named the present era the anthropocene, indicating that it is no more predominantly the biophysical factors which determine the environment for humans since about 1950, but humans themselves who influence their environment to a highest degree. Nevertheless, anthropogenic or social factors have only been marginally the topic in soil science, although related scientific communities, like the desertification community, explicitly highlighted the need for connecting human-environmental relationships to address land degradation. And while first approaches like DPSIR or the Desertification Paradigm and their linkages are already in place, still it is obvious that there is a striking gap in research in respect to the social relations of humans with soils. The proposed presentation tries to give a systematic overview about the research efforts which have been undertaken up to now and the respective approaches, both from the soil science community itself and the desertification community, as well as in other emerging initiatives like the Global Soil Partnership or the Soil-Sustainable Development Nexus.

S13.02 -6

EXPLORING THE SUCCESS FACTORS OF BROWNFIELD REGENERATION: A COMPARATIVE ANALYSES OF FOUR EUROPEAN COUNTRIES (GERMANY, CZECH REPUBLIC, POLAND AND ROMANIA)

Klusáček Petr^[1], Frantál Bohumil^[1], Martinát Stanislav^[1], Kunc Josef^[1]

^[1]Institute of Geonics Czech Academy of Sciences ~ Department of Environmental Geography ~ Brno ~ Czech Republic

The paper the main purposes are to answer following questions: What are the drivers of specific projects of brownfield regeneration? What are the factors of successful and sustainable brownfield regeneration? Are there any regional differences in the scope of four studied countries (Germany, Czech Republic, Poland and Romania)? The first part of research is based on a statistical analysis with collected databases of brownfields in order to identify significant correlations between independent (input) variables (e.g. geographical location, site characteristics, former use, ownership type, stakeholder composition, etc.) and a dependent variable (current status of the site). The result of regression analyses is a basic probability model identifying what characteristics make brownfield sites more likely to be object of investors' interest and more likely to be regenerated. Then a detailed survey of „best-practice“ regeneration projects was made identifying the key factors of „success“ in different geographical conditions and political-institutional contexts. Survey design did not define „success“ a-priori but different respondents (end-users, decision makers, investors, NGOs, urban planners, environmental experts, researchers, etc.) were asked to assess (Delphi method) a relative significance of specific factors in different geographical, economical, social and political-institutional conditions. The most important result of research is a framework of “success” indicators.

THE GLOBAL SOIL PARTNERSHIP

Vargas-Rojas Ronald*^[1], Bunning Sally^[1], Montanarella Luca^[2]

^[1]FAO ~ NR ~ Rome ~ Italy ^[2]European Commission ~ JRC ~ Ispra ~ Italy

Soils are a finite natural resource that can be considered as non-renewable in the time frame of human activities. There is increasing degradation of soil resources due to population pressures, inappropriate practices and inadequate governance over this valuable resource. FAO, with the support of the European Commission has launched the GSP in September 2011 to raise awareness of decision makers on the vital role of soil resources for achieving food security, adapt to and mitigate climate change and guarantee provision of environmental services. The vision of the GSP is for healthy and productive soils for a food secure world. The GSP as an intergovernmental mechanism will facilitate the dialogue and interaction among the various partners working on soils. The improvement of soil information and its use in developing sound soil policies and improved decision making for soil protection and management are main aims of the GSP addressing five main pillars of action: a) Harmonization and establishment of guidelines and standards; b) Strengthening of soil data and information; c) Promoting targeted soil research and development; d) Promoting sustainable management of soil resources, and e) Encouraging investment, policy and technical cooperation in soils. The GSP will be implemented by regional partnerships (national institutions and networks). This will help to identify and develop mechanisms to address the priority issues related to soils in each region, ensuring that actions will be targeted to national and regional interests. The GSP motto is Securing soil resources today, guarantying human lives tomorrow.

Soil resources in Latin America are crucial for meeting the food, fiber and fuel demands of a rapidly growing population. An outlook published in 2009 by the FAO and OECD states that the current area of cropland could be more than doubled by adding 1.6 billion hectares, mostly in Latin America and Africa. Knowledge about the soils and its functions in the region is fundamental. Improving communication to civil society and raising awareness of the importance of soil are important tasks for science. Today, soils have been acknowledged again to be the key resource, dealing with global issues such as food insecurity and climate change. Yet, communication of soil information to key stakeholders has not been achieved. With the objective of filling the communication gap between science and society, the European Commission's Joint Research Center (JRC) launched a series of thematic atlases on soil. The latest in this series is the Soil Atlas of Latin America and the Caribbean. This publication is a cooperative effort among the JRC, a wide representation of soil science community of Latin America and Caribbean countries, Europe and International Organizations such as the FAO and is supported through EUROCLIMA Project. The Atlas will include the geographic distribution of the major soil types in LAC using the World Reference Base system, highlighting the key soil forming processes and drawing attention to their potential threats, and sustainable management; a specific focus will be on the links between climate change and soils in the region.

An EU policy review showed that existing EU policies have the potential to address soil degradation in EU agriculture. Currently, the most important EU environmental directives with respect to soil quality are the Nitrates Directive and the Water Framework Directive. The Common Agricultural Policy (CAP) also plays an important role in soil conservation. Cross compliance, a horizontal tool and compulsory since 2005, contains relevant mandatory and optional measures, while within rural development, Member States can specify actions to reduce soil degradation on agricultural land under a range of measures. However, in contrast to other environmental domains (such as water and air), no coordinated piece of EU legislation exists on soils. In addition, given differences in the implementation of policy measures, the cause-and-effect models used in policy development may not always reflect what happens in the agri-environmental reality. Therefore, ten case studies identified some of the complex causal chains between factors that shape the adoption of different farming practices, and their impact on agricultural soils. Some drivers proved to be economic, while others were institutional, socio-cultural or technological.

(GERMANY) – DEFICITS AND POLICY RECOMMENDATIONS**

Hagemann Nina^{*[1]}, Prager Katrin^[2]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Economics ~ Leipzig ~ Germany ^[2]The James Hutton Institute
~ Social, Economic, and Geographical Sciences Group ~ Aberdeen ~ United Kingdom

Agricultural soil degradation is a serious issue for society as it results in long-term and sometimes even permanent damage of soils which leads to economic, social and environmental costs. The paper is based on a case study carried out in the Uckermark region (Brandenburg) as part of the SoCo project. It analyses the shortcomings of current mandatory and incentive based soil conservation policies with respect to policy design and implementation. Data was gathered through qualitative interviews with relevant stakeholders in the region and document analysis. The results show that two aspects are crucial in this respect: 1) The design of the policies that address soil conservation, and 2) the implementation strategies that are applied by local authorities. We discuss the shortcomings of the implementation strategies of soil conservation policies by outlining the deficits such as the lack of personnel, financial capacity and extension but also the lack of integration of relevant local actors and a decline in scientific support. Furthermore, we make recommendations to enhance the implementation of soil conservation policies by taking into account the issues raised by interviewees.

Soil data in Europe exists in several formats, scales and semantic representations of soil properties. Harmonization and data interoperability is one of the biggest challenges for the soil science community – enforced lately by the INSPIRE directive. The requirements to develop interoperable datasets are difficult to comprehend; the expected and possible degree of harmonization is unclear; the opportunities and requirements to provide soil information through web-based services is still fairly unknown. To regard this, the European consortium GS SOIL “Assessment and strategic development of INSPIRE compliant Geodata-Services for European soil data” worked on the establishment of a European Soil Data Infrastructure. It provides reference applications for metadata, cross-border view, discovery and transformation services. The project contributes to the harmonization and provision of interoperable soil geodata in Europe. Further examples are the soil specific thesaurus, metadata editor, catalogue service, provision of WMS and prototype WFS to serve the needs of public data requirements. It is offered via the GS SOIL portal (based on PortalU and open sources technologies (as e.g. GeoNetwork)). The following issues out of GS SOIL should be discussed: 1. Best practice recommendations a. framework for developing harmonized soil data sets (focus on mid to small-scale soil maps) b. soil specific metadata profiles 2. Lessons learned a. INSPIRE- and ISO- conform soil data exchange b. definition of a common data access framework c. technical provisions (portal functionalities, WMS, WFS), maintenance effort 3. Joint vision that leads to an operational European Soil Data Infrastructure on the basis of the presented approaches

S13.03 -6

DATA REQUIREMENTS FOR EUROPEAN ENVIRONMENTAL REPORTING AND POLICY IMPLEMENTATION

Erhard Markus^[1], Louwagie Geertrui^{*[1]}

^[1]European Environment Agency (EEA) ~ Copenhagen ~ Denmark

Soils are providing a number of essential ecosystem services for human well-being. The drafted European Soil Framework Directive identifies erosion, organic matter decline, contamination, salinization, compaction, soil biodiversity loss, sealing, landslides and flooding as the eight main soil degradation processes to which soils in the EU are confronted. The Soil Framework Directive didn't come into force so far. Soil protection is addressed in other policy frameworks such as Waste and Water Framework Directives, CAP including good farming practice, or Flood Directive. Soil related information is required for EEA's European wide regular monitoring and reporting (e.g. Climate Change, SOER2015), the EU 2020 resource efficiency target 'land-soil', the UNSD-SEEA framework for water, carbon, ecosystem accounting, and the valuation of ecosystem services in the context of Green GDP. Soil data is also needed as input and reference data for environmental assessments e.g. GMES services for land, atmosphere and climate change monitoring. There is progress but still significant gaps in soil data availability in terms of completeness (thematic and geographic coverage), spatial resolution, QA/QC (harmonization, accuracy, timeliness), and soil functional services such as water capacity or suitability in adequate spatial representation. Even more important is the urgent need for soil related monitoring which is crucial to describe changes in soil conditions and to underpin decision making with appropriate information.

S13.03 -7

THE ROLE OF EUROPEAN SOIL DATA CENTRE (ESDAC) TO EUROPEAN POLICY SUPPORT AND PUBLIC DATA REQUIREMENTS

Panagos Panos*^[1], Van Liedekerke Marc^[1], Jones Arwyn^[1], Montanarella Luca^[1]

^[1]Joint Research Centre of the European Commission ~ Institute for Environment and Sustainability ~ ISPRA ~ Italy

In the context of the European Union's Soil Thematic Strategy, policy makers require easy access to soil data and information of various types and scales to assess the state of soils at European level. To satisfy this need, the European Commission and the European Environment Agency decided to establish the European Soil Data Centre (ESDAC), located at the European Commission's Joint Research Centre. The ESDAC is one of ten environmental data centres that have been established in support of policy development, implementation and monitoring by the European Commission's Directorate General for Environment. The ESDAC, located at <http://esdac.jrc.ec.europa.eu>, has become the focal point for soil data and information at European Union level by hosting a series of soil products and web-based tools that allow access to the data. The establishment and the evaluation of harmonised databases should facilitate improved soil protection measures. The ESDAC supports an increasing number of customers from the European Commission and Member States. They range from policy makers, public organizations and local authorities, and public administrations to research institutes, technical institutions, universities and schools, modeling groups, research projects and citizens. Most of the datasets are used for research purposes (Modeling, FP7 projects, PhDs, etc). ESDAC data and information are highly relevant for the development, implementation and assessment of a number of EU policy areas: agriculture, soil protection, bio-energy, climate change, water protection, food security, nature protection, spatial planning, development policy, health, research and sustainable development.

Soil Critical Zone is the intersection area of pedosphere, biosphere, hydrosphere, lithosphere and atmosphere. Critical Zone Observatories (CZOs) network enables studies of important physical, chemical, and biological interfacial processes and reactions occurring over a range of spatial and temporal scales. These processes impact mass and energy exchange necessary for biomass productivity, chemical recycling, and water storage. Detailed soil morphological, physical, chemical and microbiological characterization of different soil genetic horizons at soil profile scale was commenced in 2010 at four field sites with successful track records of research and data collection, which form the SoilTrEC Project network of European Critical Zone Observatories (CZOs). The 4 European CZOs represent key stages of soil development and degradation. Three replicates at each sampling site selected within these CZOs were sampled to represent the spatial variability of soil parameters and to identify soil processes with statistics. Taking sets of replicate soil pits and carrying out a common set of measurements for each site provided quantitative data needed for mathematical modelling of food-webs, carbon dynamics, geochemical processes and reactive transport. The primary output from this modelling exercise will be an analysis of the dominant soil processes and their rates at different stages of the soil life cycle. The presentation will report the sampling methodology and determined soil characteristics with example for one soil profile in triplicate focusing on (i) the composition and the stability of soil aggregates and their size distribution within soil profiles and (ii) the soil (geo)chemistry and (micro)biology including the microbial community structure.

Soil studies across substrate age gradients (chronosequences) have enhanced our understanding of the directions and the rates of biogeochemical processes under different ecological conditions. Biogeochemical processes, such as soil organic matter (SOM) and nutrient dynamics, can act in different timescales depending on climatic conditions, plant cover and biomass inputs as well as living organisms. SOM is a main driver for soil development and the build-up of soil structure and is therefore governing the main physical and chemical properties of soil. However, SOM dynamics in the initial stages of soil development as well as the stability of SOM within aggregates and by sorption on soil mineral surfaces are still poorly understood. Even less is known about the impact of different land uses on these short to medium-term processes. In the present study we assess SOM quantity and its chemical composition within different micro- and macro-aggregates of genetic soil horizons, developed under forest, grassland and cropland. The studied soils of a chronosequence comprise an age gradient of approximately 5000 years in the Marchfeld region (Austria). This allows for investigating the influence of SOM, physico-chemical soil properties as well as soil microbial processes on soil structure build-up with time. Results of our study show that ecosystems progressively evolve through biogeochemical processes at different time scales and can be strongly altered by anthropogenic land management.

S13.04 -3

A COUPLED CARBON, AGGREGATION, AND STRUCTURE TURNOVER MODEL FOR TOPSOILS

Stamati Fotini^{*[1]}, Nikolaidis Nikolaos^[1], Banwart Steve^[2], Blum Winfried^[3]

^[1]Technical University of Crete ~ Department of Environmental Engineering ~ Chania ~ Greece ^[2]University of Sheffield ~ Kroto Research Institute ~ Sheffield ~ United Kingdom ^[3]University of Natural Resources and Applied Life Sciences ~ Institute for Soil Science ~ Vienna ~ Austria

Current multi-pool soil organic carbon (SOC) models have been a major improvement over the single carbon ones. However, they are not always able to capture soil saturation capacity and give reliable predictions for climate change effects, since they do not account for environmental constraints, like physical protection. In this work we developed a soil carbon, aggregation, and structure (CAST) turnover model based on the proposed mechanism of aggregate formation that suggests that macro-aggregates are formed around particulate organic matter, followed by the release of micro-aggregates. A simple mechanistic Nitrogen model was also developed. The CAST model was evaluated by field data of cropland to set aside conversions in Greece (fine textured-Mediterranean) and Iowa (coarse textured-humid continental). The model was able to capture the carbon content and the C-to-N ratio of the pools comprising the three aggregate types (macro-aggregates: >250 μm , micro-aggregates: 53-250 μm , silt-clay sized aggregates: <53 μm) in both sites. The soil systems reached maximum macro-aggregation/porosity and minimum bulk density after 7 and 14 years in Greece and Iowa, respectively. Afterwards, macro-aggregate disruption presented a constant seasonal pattern and any further SOC increase was due to micro-aggregation resulting in the increase of bulk density and decrease of porosity towards to a steady value. The CAST model can assist in revealing the primary factors that determine SOC, aggregation, and structure turnover in different ecosystems and for predicting the response of the soil system to management practices, land use changes, and climate change in order to design/optimize the appropriate measures/practices.

**CHARACTERISATION OF THE MICROBIAL COMMUNITIES WITHIN SOIL AGGREGATES
DEVELOPED UNDER DIFFERENT LAND MANAGEMENT**

Menon Manoj^[1], Zhang Dayi^[1], Van Der Zaan Bas^[2], Lair Georg^[3], Lehtinen Taru^[3], Huang Wei^[1], Banwart Steve^[1]

^[1]Kroto Research Institute, University of Sheffield ~ Civil and Structural Engineering ~ Sheffield ~ United Kingdom

^[2]Deltares ~ Deltares ~ Utrecht ~ Netherlands ^[3]Institute of Soil Research Department of Forest and Soil Sciences ~ University of Natural Resources and Life Sciences (BOKU) ~ Vienna ~ Austria

It is well established that microbes as well as their metabolic products play a vital role in the formation of soil aggregates. The relationship between microbial diversity (and their functions) and soil aggregate properties like size, composition, physical structure, mechanical stability and nutrient status is poorly understood. Furthermore, we propose that aggregates provide essential ecological niches for soil function: to transform nutrients, store carbon, store and transmit water, and attenuate contamination from infiltration. In this proof-of-concept study, we hypothesize that the aggregate characteristics -beside particle size distribution and mineralogy- are controlled by the total amount and diversity of microbes (including specific functional groups) as well as their products (e.g. EPS). The aim of this study is to understand the microbial communities and their function in different aggregate size fractions developed in soil of similar age but under three land management (forest, grassland and agriculture) practices prevailing in Marchfeld Critical Zone Observatory (CZO). The stability of the aggregates from the topsoil has been assessed previously by our collaborators (Kercheva et al 2011). In the proposed work, the DNA from various aggregate fractions (<0.25, 0.25-0.5, 0.5-1.0, 1-2, 2-5, 5-10mm) from different land management will be extracted and microbial community and functional groups will be studied using DGGE and qPCR. The results will be linked to various physical and geochemical soil properties in order to get insights on aggregate formation.

OXIDE NANOPARTICLES IN A PODZOL SOIL: EXTRACTION AND SIZE DISTRIBUTION

Regelink Inge C.*^[1], Weng Liping^[1], Van Riemsdijk Willem^[1]

^[1]Wageningen University ~ Soil Quality ~ Wageningen ~ Netherlands

The topic of nanoparticles in environmental systems is receiving increasing interest. Engineered and natural nanoparticles can be expected to show similar behavior in environmental systems. In this paper we aim to understand the factors controlling the dispersion/aggregation of oxide nanoparticles in soils. Soil samples from a podzol soil with a high Fe- and Al (hydr)oxide content were used. We analyzed the amount, composition and size-distribution of dispersible oxide nanoparticles in various extracts using AF4 (Asymmetric-Flow-Field-Flow-Fractionation) coupled to HR-ICP-MS. Three different extracts were used to disperse the particles: a dilute NaCl solution, a NaOH solution (pH 9.3) and a pyrophosphate solution (pH 8.5). The amount of dispersed Fe- and Al-(hydr)oxide nanoparticles increased in the order of NaCl < NaOH < pyrophosphate. In pyrophosphate, 27% to 69% of the amorphous Fe-(hydr)oxides (Fe extracted with ammonium oxalate) were extracted as nano-sized particles (<130 nm). Smallest (hydr)oxide particles are a few nanometers only and weight-average hydrodynamic diameters are between 25 and 28 nm. Based on the minor change in phosphorus to oxide ratio with increasing size, we suggest that the specific reactive surface area of the particles is almost constant, which indicates that the larger nanoparticles are aggregates composed of smaller nanoparticles. The release of mineral nanoparticles coincides with the release of soil organic matter, which shows the importance of organic matter for the aggregation behaviour of (hydr)oxide particles.

S13.04 -6

AN INTERNATIONAL INITIATIVE FOR CRITICAL ZONE OBSERVATORIES (CZO) AND RESEARCH ALONG GLOBAL ENVIRONMENTAL GRADIENTS

Banwart Steven*^[1]

^[1]University of Sheffield, Kroto Research Institute ~ Civil and Structural Engineering ~ Sheffield ~ United Kingdom

Critical Zone scientists convened an international workshop during November 8-9, 2011, at the University of Delaware, USA. The meeting included 87 scientists from 15 countries presenting current research and new opportunities at 25 CZOs worldwide. The aim was to prioritise science questions to drive Critical Zone Observatory (CZO) research during the coming decade. The broad research challenges are to understand the geological and evolutionary processes that shape the Critical Zone, and the physical, biological and chemical processes that result and deliver Critical Zone ecoservices to humanity. These include production of soil, storage of carbon, nutrient transformations, providing biological habitat, maintaining the terrestrial gene pool, base flow to surface waters, groundwater recharge, attenuating soil and water pollution, and many others. Six science questions were divided into 2 themes: 1) understanding long-term evolution of the near-surface Earth environment as antecedent conditions to modern environmental change, and short-term changes that require prediction and management responses for humans to mitigate and adapt to the environmental impacts. The primary result is the outline design of international networks of CZOs that are geographically located along environmental gradients at planetary scale. This will allow the study of Critical Zone responses to key environmental variables representing, e.g. land use change and global warming. This effort aims to be a leading integrating activity for environmental geosciences research worldwide. The meeting received financial support from the USA National Science Foundation and was part of commissioned activity of the European SoilTrEC project, funded by the European Commission.

**HOLISTIC INTEGRATED DECISION SUPPORT SYSTEMS FOR BROWNFIELD
REVITALIZATION – KNOWLEDGE TRANSFER CHALLENGES IN TOOL DEVELOPMENT**

Morio Maximilian*^[1], Sebastian Schädler^[1], Michael Finkel^[1]

^[1]University of Tübingen ~ Centre for Applied Geoscience ~ Tübingen ~ Germany

With land becoming a scarce resource in many regions, revitalizing these so-called brownfields becomes more and more attractive, representing an opportunity for sustainable urban development. The process of managing and revitalizing brownfields requires a holistic view that considers ecological, economical as well as sustainability aspects. Integrating evaluation methods and communicating results of the latter to the stakeholders from these different disciplines requires a common language which may include clarification and simplification of various assessment aspects. Decision support systems (DSS) that aid the assessment and revitalization process of brownfields and adequately provide such integration, still need to be developed. Given that each brownfield has different characteristics and problems, a single DSS may not be capable of considering all relevant aspects. Moreover, the required involvement and participation of expert and non-expert stakeholders, whose knowledge and expectations have to be transferred into the software tools, determines the abstraction and generalization of the chosen methods. Finally, the evaluation methods have to be implemented into user friendly software that is suitable for the largest possible fraction of stakeholders and that covers all relevant aspects of brownfield redevelopment. We exemplify the development of one specific DSS and its continuous evolvement through various national and international research projects. This DSS software, which has been initiated during the BMBF research program REFINA, was extended to a megasite management system (SAFIRA II MMT), and is proposed to be transferred to a tailored web-based DSS tool within the EC research program TIMBRE.

SOME CRITICAL ISSUES ON RISK ASSESSMENT AND REMEDIATION OF INDUSTRIAL CONTAMINATED SITES

Li Fasheng^{*[1]}, Guo Guanlin^[1], Marcomini Antonio^[3], Critto Andrea^[3]

^[1]Chinese Research Academy of Environmental Sciences ~ State Key Laboratory of Environmental Criteria and Risk Assessment ~ Beijing ~ China ^[2]Chinese Research Academy of Environmental Sciences ~ State Key Laboratory of Environmental Criteria and Risk Assessment ~ Beijing ~ China ^[3]University Ca' Foscari ~ Department of Environmental Sciences and Centre IDEAS ~ Venice ~ Italy

Recently, the accelerated industrialization and urbanization generated numbers of contaminated sites in China, which are leading to environmental damage and arousing the public concern. Risk assessment and remediation of the contaminated land are urgently needed for the future land development and environmental safety. During the past five years, government and institutes developed series of policies, regulations and guidelines for the risk management of contaminated sites, but some critical issues still need further improvements: the exposure factors as well as the site-specific parameters should be localized and optimized according to the native condition; the maximum acceptable risk level (ranging from 10^{-4} to 10^{-6} , and related to the risk based remediation thresholds) should be feasible and effective according to national economic development; how to define a scientifically sound and cost effective sampling plan in order to optimize the characterization of site contamination; how to develop and screen out the most suitable remediation technologies for different sites based on cost-effective, aesthetic, modern and green requirements. These critical issues should be taken into consideration in order to provide the better settlement for risk assessment and remediation of industrial contaminated sites in China.

TREE CORING AS A PHYTOSCREENING METHOD

Algreen Mette^{*[1]}, Rein Arno^[1], Trapp Stefan^[1]

^[1]Technical University of Denmark (DTU) ~ Department of Environmental Engineering ~ Kgs. Lyngby ~ Denmark

Phytoscreening where plants are used as an indicator of subsurface pollution may be a useful screening method for subsurface plumes, because several pollutants are transferred readily into vegetation. Wood and/or other plant parts can then be sampled for detection as well as for monitoring of soil and/or groundwater contamination. Tree coring as a phytoscreening method has been investigated. Tree cores of poplar (populus), willows (salix) and other species have been sampled at different sites in Europe. Samples have been taken from reference sites without contamination and from test sites contaminated with different compounds such as heavy metals, organic solvents and PAH. The use of the method and the evaluation of the results appear to be specific to compounds. Detections of compounds in wood not necessarily indicates contaminated soil/groundwater but may be due to natural background levels, e.g. for some metals, or due to pollution from air. Results from samples taken on a test site should therefore, always be compared with samples from a nearby reference site. The method is semi-quantitative, and bioaccessibility and bioavailability of the compounds, and the plant biology have shown to have impact on the method. For organic solvents correlations between the concentrations in the wood and soil/ground have been seen. For metals the case is more difficult, and statistical analyses seem to be needed to compare test samples and references samples, to identify elevated concentrations in the wood.

^[3]Technical University of Civil Engineering Bucharest ~ Hydrogeology ~ Bucarest ~ Romania

Washing is among the few systematic alternatives to remove contaminants from soils, specially in case of metals, which are not degradable and that often have high vaporisation temperatures. In addition, it has the advantages to help the physical separation of macroscopic contaminants in on-site operations, and the removal of all micro-pollutants simultaneously by using an adapted train of chemical reactions. Efficient and wide-targeted reactions are needed to realise fast decontamination operations. Therefore, one of the main limitations of chemical washing over large contaminated sites, are costs associated with the use of chemical reagents and the treatment of huge amounts of wastewater. To be economically feasible, chemical agents must be recovered and reused at least several times by using simple and cheap treatments. Furthermore, they must be biostable and not accumulated in soils during repeated extractions. Finally, foams can replace advantageously solutions because of their exceptional properties that fit better with in-situ treatments, their wide-targeting of hydrophobic pollutants and the large reduction of wastewater volume to treat after their destabilisation. Here we will present some technologies developed in our laboratory, within the EU project TIMBRE, to reuse aqueous solutions of ligands and foams to mobilise heavy metals and a wide range of VOC and SVOC compounds from polluted soils. Remediation performances and fluids reuse performances will be presented on contaminated soils obtained from an old iron works in Hunedoara (Romania) as well as results from an on-site pilot test.

S13.05 -5

TIMBRE EXPERT SYSTEM AS INFORMATION PLATFORM FOR INNOVATIVE AND WIDELY APPLICABLE STRATEGIES, TECHNOLOGIES AND SOLUTIONS FOR BROWNFIELD REGENERATION

Pizzol Lisa^[1], Rizzo Erika^[1], Critto Andrea^[1], Marcomini Antonio^[1]

^[1]University Ca' Foscari Venice ~ Department of Environmental Sciences, Informatics and Statistics ~ Venice ~ Italy

Brownfield regeneration is an essential step to realize sustainable land management in European Member States. However, the success in brownfield regeneration is unsatisfying in terms of financial and eco-efficiency or social acceptance. Identified obstacles for an effective regeneration are (i) the abundance of strategies, tools, documented case studies and remediation technologies available at the EU level as well as (ii) the difficulties in adapting them to cultural, regional and site-specific requirements. Moreover, the non-visibility of already available, useful and innovative technologies and decision making processes is the reason that problem owners, managers, local authorities and other stakeholders do not regenerate brownfields using the best available technology and decision support systems measures. The 7th Framework Programme project TIMBRE (Tailored Improvement of Brownfield Regeneration in Europe) starts from these considerations and aims at overcoming these barriers by providing brownfields' owners, local authorities and stakeholders with a web-based and target-oriented customizable decision support toolbox. This contribution focuses on the presentation of the timbre expert system database, developed in TIMBRE Work Package 1, which collects the available information on previous projects, programs, and other activities focused on the regeneration of brownfields. The database data collection is based on a conceptual framework, composed of the main phases of the brownfield regeneration process, which has been developed in strong collaboration with the timbre case studies stakeholders. On the basis of the identified brownfield remediation process phases, the available methods, tools, strategies, best practices, and technologies, expressly developed for brownfield rehabilitation are collected and classified.

S13.05 -6

KNOWLEDGE AND DECISION MAKING IN BROWNFIELD REVITALIZATION: CROSS-CULTURAL VARIATIONS WITHIN EASTERN EUROPE

Bleicher Alena^[1], Alexandrescu Filip^{*[1]}, Gross Matthias^[1]

^[1]Helmholtz Centre for Environmental Research ~ Department of Urban and Environmental Sociology ~ Leipzig ~ Germany

In most industrialized countries the revitalization of contaminated brownfields is seen as a major challenge for sustainable regional development. This challenge demands collaborative action between diverse actors on multiple scales (local, regional, national, European). This presentation includes a selection of preliminary results from the EU research project TIMBRE (Tailored Improvement of Brownfield Regeneration in Europe) that aims to analyze social actors' strategies of "translating" European and national legal regulations into their local needs and expectations in several Eastern European contexts. The main focus of the research is the role and types of knowledge that different actors acquire during a brownfield revitalization process, how this knowledge is marshaled and how it is deployed in decision making processes. Knowledge is generated and retrieved by actors from different sources, including local site-specific sources, regional and national-level regulations for brownfield revitalization and scientific sources. The ways in which this knowledge is assembled and assessed by actors, strategies on how gaps are filled and new opportunities are sensed are pivotal for our understanding of the cultural contexts of decision making processes. This presentation will built on a first set of analyses of interviews and focus group meetings in Hunedoara, Romania in 2011 and 2012 to illustrate how decision making on the ground can be made by constructively transforming EU regulations into local specificities to develop unique spaces to maneuver. These preliminary results will be used as comparative material for cases in the Czech Republic, Poland, and Germany.

ASSESSING BIOCHEMICAL AND BIOMOLECULAR GRADIENTS ALONG AN OMBROTROPHIC PEAT BOG PROFILE

Puglisi Edoardo^{*[1]}, Cappa Fabrizio^[1], Zaccone Claudio^[2], Miano Teodoro^[3], Trevisan Marco^[4]

^[1]Università Cattolica del Sacro Cuore ~ Istituto di Microbiologia ~ Piacenza ~ Italy ^[2]Università di Foggia ~ Dipartimento di Scienze Agro-ambientali, Chimica e Difesa Vegetale ~ Foggia ~ Italy ^[3]Università di Bari ~ Dipartimento di Biologia e Chimica Agro-forestale ed Ambientale ~ Bari ~ Italy ^[4]Università Cattolica del Sacro Cuore ~ Istituto di Chimica Agraria ed Ambientale ~ Piacenza ~ Italy

Ombrotrophic peat bogs are not directly in contact with groundwater: since their genesis is related only to wet and dry deposition they are considered natural archives of extreme importance for the assessment of past ecological, environmental and climatic events. Etang de la Gruère is an ombrotrophic Swiss bog representing the longest continuous record of atmospheric deposition in continental Europe (corresponding to ca. 15,000 years of peat formation). Aim of the present study is to assess, in ca 20 samples along the peat bog profile, the presence and distribution of two very important classes of biomolecules: DNA and lipids. PCR-DGGE analysis of DNA targeting total bacteria and archaea allowed the identification of biodiversity patterns that clustered according to the profile depth and chemical analyses. It was found that the microbial communities changed significantly below ca 45 cm, where conditions are anoxic and molecules with higher molecular mass and degree of condensation are observed. Acidobacteria dominated the most superficial samples, while methanomicrobia were more common in the deepest samples. It was also found that the homologies scores decreased with depth, thus pointing to a less known microbial community composition in the oldest samples. Lipid analyses are now being carried out to integrate and extend the findings at DNA level. Specifically the analyses are focusing on phospholipid fatty acids (PLFAs) and tetraether lipids, which are respectively indicators of bacterial and archaeal microbial communities. In the case of tetraether lipids, their possible application as "paleo-thermometers" is also being tested.

Ombrotrophic peatlands are usually considered as a valuable repository of high-quality climatic signals because their only source of water is from precipitation. For this reason, they constitute an authentic record of information about past and present patterns in global climatic change and the impact of historical natural and human activity in causing trace element contamination. In the province of Belluno, bogs of major interest are located in Danta di Cadore (1400 m a.s.l.) and Coltrondo (1800 m a.s.l.). This study aims to sample these bogs for reconstructing past climate and environmental conditions. Prior to any expensive and time consuming chemical procedure and analysis, measurement of major and trace elements in peat profile using the non-destructive X-Ray Fluorescence core scanning was performed. This method provides high resolution geochemical data that helps to document the natural geochemical processes which occur in the peat profiles and their possible effect on the distribution of trace elements. The presence of trace metals, heavy metals and REE will be also detected in digested peat solution using ICP-MS and ICP-OES. Using appropriate age dating methods, suitable age-depth models and careful determinations of trace element concentrations, it is possible to reconstruct the changing rates and the predominant sources of a wide variety of atmospheric trace elements. In addition, the biological relevance of these processes are examined in particular using spatial relationships in pollen distribution and their correlations to modern climate as a guide to interpreting pollen patterns recorded in the past and to reconstructing vegetation history.

**COMPLEX PEDOGENESIS IN THE EOPLEISTOCENE PALEOPEDOCOMPLEX OF THE
NORTHERN CISCAUCASIA: POLYGENETIC MODELS**

Shorkunov Ilya*^[1]

^[1]Institute of Geography Russian Academy of Sciences ~ Soil Geography and Evolution Dept. ~ Moscow ~ Russian Federation

Paleopedocomplex was investigated in the Temizhbeksky section which is located in the natural outcrop of the Kuban river and has a thickness of about 50 m. Paleopedocomplex was formed in the Eopleistocene, it consist's of six paleosoil horizons lying in five lithological layers. Paleosoil horizons belong's to four individual truncated paleosoil profiles. The upper profile lying in the single litho-layer and consist's of one horizon which has vertic, stagnic and calcic features. Temporal and spatial relations of these features could be explained by three evolution stage of pedogenesis. The second profile lying in the single litho-layer and formed by two horizons of stagnic luvisol which also has vertic and calcic features referred to the younger upper paleosoil. The third profile transfixing two different litho-layers by cambic and calcic horizons. Paleosoil also has weak vertic and stagnic features which could be explained by the soil self-development in a low-amplitude climate fluctuations. The lower profile lying in the single litho-layer and formed by the single calcic horizon with gleyic and vertic features. Pedogenesis could be explained by polygenetic model. Thus, investigated paleopedocomplex keeps information not less than twelve stages of litho- and pedogenesis. The term "polygenesis" has three different meanings in this case. The first – the pedocomplex polygenesis which is in a complex sequence of lithological layers and soil horizons. The second is in evolution of the individual paleosoil profiles in the pedocomplex which reflect a climate change. And the third is in inheritance of buried soil horizon by later pedogenesis.

CONFRONTATION OF CARBONATE BEDROCK WITH POLYGENIC ALLOCHTHONOUS MATERIAL: WHICH PARENT MATERIAL PREVAILS IN SOIL EVOLUTION?

Martignier Loraine^[1], Adatte Thierry^[1], Verrecchia Eric^[1]

^[1]University of Lausanne ~ Institute of Geology and Palaeontology ~ Lausanne ~ Switzerland

The geological substratum of Swiss Jura Mountains is composed of Mesozoic limestones and marls. Therefore, it would be expected that pedogenesis follows an evolutionary pathway mostly affected by carbonate dynamics. Nevertheless, the study of a soil toposequence reveals that most of the soil profiles exhibit a clear lithological discontinuity between upper and lower soil horizons, the deepest ones arising from bedrock weathering. Acidic pH values are measured in surficial horizons. They enhance processes such as brunification and clay leaching. Consequently, the way in which lithodependence impacts soil development is questioned. Superficial deposits are identified along the studied toposequence in order to decipher the polygenic origin of the mineral phase. Their distribution records the succession and interactions of the different transport and deposition dynamics that modelled the landscape since the last glaciation. The in situ weathered material and the surficial allochthonous deposits are discriminated through multivariate statistical analyses of mineralogical data and grain size distribution of the soil mineral fraction. Results confirm the polygenic origin of the surficial deposits and demonstrate a contribution of allochthonous minerals in the upper soil horizons. Potential sources of this mineral phase are documented using soil micromorphology and scanning electron microscopy, combined with field observations. Provenance of allochthonous material is attributed to deflation of Alpine moraines situated on the Swiss Plateau during the late glacial period. These aeolian episodes formed loess deposits on the Jura crests. According to their depth, these deposits influence present-day pedogenesis and significantly lessen the contribution of the carbonate geological substratum.

CORRESPONDENCE BETWEEN VERTICAL PROFILE OF SOIL COMPACTNESS AND INTENSITY OF LAND GRADING PROCESS IN URBAN GREEN PARKS, TOKYO METROPOLIS

Uoi Natsuko*^[1], Murata Tomoyoshi^[2], Watanabe Makiko^[1]

^[1]Tokyo Metropolitan University ~ Department of Geography, Graduate School of Urban Environmental Science ~ Tokyo ~ Japan ^[2]National Institute for Environmental Studies ~ Water and Soil Environment Division ~ Tsukuba ~ Japan

Expansion of urban area causes specific environmental problems in metropolis, such as “urban heat island” and “urban flood”. Urban soils develop under such circumstances associated with intensive stress of human activities and their properties may further change by various processes of human activities. Nevertheless, soils in urban area may have miscellaneous functions to create sustainable urban environment such as mitigation of heated atmosphere, recovery of infiltration capacity, conservation of bio-diversity, storage of carbon, and so on. Two historical parks in Tokyo Metropolis, the Kitanomaru and the Shinjuku-Gyoen parks, were examined in this study to understand basic characteristics of soil development of urban soils in consideration with land use history, land creation method, current land coverage and management. In this study, we focused on soil physical properties to develop a convenient methodology for conducting soil survey in urban green parks. Vertical profiles of soil compactness were obtained using a 1 meter cone penetrometer at 134 and 80 points in Kitanomaru and Shinjuku-Gyoen parks, respectively. The obtained profiles were classified 18 groups in terms of the pattern of the soil compactness. Spatial analysis using GIS showed a significant correspondence between the characteristics of vertical soil compactness and land creation history. It could be concluded that vertical soil compactness is a useful index to understand the intensity of grading process in urban parks.

S01.01-P -6

DOES SPECIFIC PEDOGENESIS OCCUR IN TECHNOSOLS DEVELOPING ON IRON INDUSTRY WASTES DEPOSITS?

Huot Hermine^{*[1]}, Simonnot Marie-Odile^[2], Marion Philippe^[3], Yvon Jacques^[3], De Donato Philippe^[3], Morel Jean-Louis^[1]

^[1]Laboratoire Sols et Environnement ~ Université de Lorraine - INRA ~ Vandoeuvre-lès-Nancy ~ France ^[2]Laboratoire Réactions et Génie des Procédés ~ Université de Lorraine - CNRS ~ Nancy ~ France ^[3]Laboratoire Environnement et Minéralurgie ~ Université de Lorraine - CNRS ~ Vandoeuvre-lès-Nancy ~ France

Technosols include soils dominated or strongly influenced by human-made materials. But whether pedogenesis of Technosols is governed by specific processes in comparison to those occurring in natural soils remains unknown. With this aim in view, a Technosol derived from purely anthropogenic materials was investigated. It has formed on a former settling pond of sludge generated by iron industry. Probably abandoned in the mid-20th century, this pond has been covered by a diversified forest. The soil is composed of contrasted layers. An organic layer has developed at the surface. Composition and properties of the soil materials were studied in the first two meters of the profile under root influence. Elemental composition was dominated by Fe, Mn, Ca and Si and revealed very high contents in heavy metals, up to several percents for Pb and Zn. The soil was slightly alkaline (5-30 % carbonate). Mineralogy was characterized by poorly crystalline phases mainly aluminosilicates, Fe and Mn (hydr)oxides, Ca carbonates and sulfates. Bulk density was lower than 0.7 g cm⁻³. Porosity was higher than 75 % (v/v) with a majority of micropores. Water retention capacity and specific surface were high. Thus, despite its anthropogenic parent materials, this Technosol displays properties comparable to those developed in natural soils, such as volcanic, carbonated or manganese bearing soils. But conditions of formation of these soils are rarely concomitant in natural environments. This leads to wonder if human factor (nature of parent material, mixing) could create particular conditions allowing unusual combinations of natural soil-forming processes.

EFFECTS OF THE ADDITION OF ALKALI-SOLUBLE ORGANIC MATTER EXTRACTS FROM TWO COMPOSTS MADE FROM OLIVE MILL WASTE ON CHEMICAL PROPERTIES OF A CALCAREOUS SOIL

Bautista Carrascosa Inmaculada^[2], García De La Fuente Rosana^[3], Oliver Talens Joana^[2], Lidón Cerezuela Antonio^[3], Fornés Sebastiá Fernando^[3]

^[1]Universitat Politècnica de Valencia ~ Química ~ Valencia ~ Spain ^[2]Universitat Politècnica de Valencia ~ Grupo Reforest. Ingeniería Hidráulica y Medio ambiente ~ Valencia ~ Spain ^[3]Universitat Politècnica de Valencia ~ Instituto Agroforestal Mediterráneo ~ Valencia ~ Spain

Calcareous soils, which are widespread in the Mediterranean basin, are characterized by a high chemical reactivity, due to calcium carbonate precipitation-dissolution processes, in which biological activity also plays an important role by means of CO₂ release. The application of liquid organic amendments has been proposed as a nutrient and organic matter source for agricultural purposes. The aim of this work was to study the influence of two different alkali-soluble organic matter (ASOM) extracts prepared from composted two-phase olive mill waste –also called ‘alperujo’, which is generated by the olive oil extraction industry– on several chemical characteristics of a calcareous soil, by using rates within the range of 200 to 6400 mg C kg⁻¹ soil. The ASOM materials were extracted with KOH 1M (compost:extractant proportion 1:3, w:v) during 24 hours at 70°C. The extracts exhibited high pH and electrical conductivity (EC) values. To study the immediate effects of the addition of ASOM extracts, they were mixed with the soil at the abovementioned rates and a short-term extraction (after two hours) with distilled water (soil:water extract 1:1, w:v) was carried out for pH, EC and water-soluble organic carbon determinations. These parameters were also studied after 6 months in order to know the influence of ASOM application on soil in a longer term. The results of these experiments showed that both pH and salinity increase was lower than it was theoretically expected, being these effects possibly related to cation exchange, CaCO₃ precipitation and organic carbon adsorption at the solid phase of the soil.

ENHANCED GROWTH OF CORN AND IMPROVEMENT OF SOIL QUALITY ON THE APPLICATIONS OF CLAY MINERALS TO SOIL

Lee Sangseung^{*[1]}, Lee Seok Eon^[2], Chung Keun Yook^[2], Kim Deok Hyeon^[2], Kwon Sang Moon^[2], Woo Sun Hee^[3], Lee Moon Soon^[4]

^[1]Eum Seong Agricultural Technology Center ~ crop ~ Eum Seong Gun ~ Korea, Republic of ^[2]Chungbuk National University ~ Department of Environmental Biology and Chemistry ~ Cheongju ~ Korea, Republic of ^[3]Chungbuk National University ~ Department of Crop Science ~ Cheongju ~ Korea, Republic of ^[4] Chungbuk National University ~ Department of Industrial Plant ~ Cheongju ~ Korea, Republic of

This study was initiated to evaluate the effect of the clay minerals, such as illite, phyllite, zeolite on the growth of corn and soil quality. The clay minerals were applied to the field soil at a rate of 6,000kg/ ha. pH in the soils treated with illite, phyllite, and zeolite, and measured once weekly, was increased, compared to untreated soils. The organic matter content were 31%, 34%, and 29% higher in the treatments of illite, phyllite, and zeolite, than in the untreatment, respectively. C.E.C. were 13%, 15%, 17% higher in the treatments of illite, phyllite, zeolite than in the untreatment, respectively. The cation K were 10%, 13%, and 12% higher in the treatments of illite, phyllite, and zeolite than in the untreatment, respectively. The bacterial counts(CFU/g) on NA media for soil samples from the rhizosphere soil were 2, 2.1, and 2.1 times higher in the illite, phyllite, and zeolite treatments than in the untreatment. The actinomyces counts(CFU/g) on a PDA media were 1.8, 1.7 and 2.5 times higher in the illite, phyllite, zeolite treatments than in the untreatment. The fresh weights of corn per one were 40%, 33%, and 28% higher in the treatments of illite, phyllite, zeolite, than in the untreatment, respectively. Based on the results obtained from the study, it appears that the application of clay minerals to soil also improve the soil quality.

ENHANCED GROWTH OF RED PEPPER BY THE APPLICATIONS OF CLAY MINERALS TO THE BED SOIL AND PROTEOMIC ANALYSIS

Chung Keun Yook*^[1], Lee Seok Eon^[1], Kwon Sang Moon^[1], Woo Sun Hee^[2], Nam Ju Hyun^[3], Choi Jong Soon^[3]

^[1]Chungbuk National University ~ 1Department of Environmental Biology and Chemistry ~ Cheongju ~ Korea, Republic of ^[2]Chungbuk National University ~ Department of Crop Science ~ Cheongju ~ Korea, Republic of ^[3]Korea Basic Science Institute ~ Proteomics Team ~ Daejeon ~ Korea, Republic of

The use of bed soil has heavily been increased with the development of raising technology of good quality of seeding such as using plug tray since the development of horticultural industry of 1990. Requirement of bed soil for the raising of seeding should have good physical, chemical, and biological properties and consider economical aspect. Materials for raising of seeding in the Korea and foreign countries are inorganic materials, zeolite, vermiculite, perlite, organic materials, saw dust, peat moss, The objectives of the study were to evaluate the effect of clay minerals on the growth of red pepper in the bed soils and to perform the proteome analysis in involved in its growth. Four clay minerals such as, illite, phyllite, zeolite, and bentonite were used in this study. Red pepper was used as a model vegetable crop and grown in the green house. The treatments of four clay minerals such as illite, phyllite, zeolite, and bentonite to the bed soils enhanced the growth of red pepper. Compared to the untreated, the growth of red pepper were 29, 46, 37, and 32% higher in the treatments of illite, phyllite, zeolite, and bentonite than in untreated, respectively. Also, dry weight of root of red pepper were 13, 24, 11, 10% higher in the treatments of illite, phyllite, zeolite, bentonite, than in untreated, respectively. Dry weight of stem of red pepper were 116, 120, 131, 130% higher in the treatments of illite, phyllite, zeolite, bentonite, than in untreated, respectively

ENVIRONMENTAL INTERPRETATION OF TWO HOLOCENIC FOSSIL SOILS IN SOUTHERN ITALY.

Dimase Antonio Carmine*^[1]

^[1]Università degli Studi di Firenze ~ Dipartimento di Scienze delle Produzioni Vegetali, del Suolo e dell'Ambiente Agroforestale (DiPSA) . ~ Firenze ~ Italy

In the Holocene, the hills adjacent to Ionian coast of Basilicata, S. Italy underwent to strong erosion. Recently, the spectacular forms of land degradation attracted many Italians and foreign geologists. The purpose of this pedological study is to identify the causes of the erosion, either climatic or anthropic, and to establish the chronology of these events. The two buried soils studied in a pedostratigraphic section, nearly 20 metres high, are both Inceptisols, the S1 is at about 10 metres from the surface, the S2 at 8 metres. The results of soil morphology, micromorphology, chemical analyses and radiocarbon dating of soil organic matter and charcoal lead to the following conclusions: 1) The pedogenesis of S1, started in the middle Holocene; the strong erosion/sedimentation phase that preceded the genesis of this soil is attributed to a climatic humid phase. For the S2 the erosion/sedimentation phase is anthropic, that occurred during the Greek-Roman time. 2) The 8 m of sediments over S2 are the consequence of human impact that took place between the end of XVII century and the beginning of XIX, due to the dramatic increase of population and the social and political changes of that time. Keywords: Fossil soils, climatic changes, human impact, radiocarbon dating.

S01.01-P -11

FUNCTIONING OF PALEOCRYOGENIC SOIL COMPLEXES: STABLE PATTERN OF RELICT FEATURES DESPITE THE CHANGEOVER OF KEY CONTROL FACTORS

Arkhangelskaya Tatiana*^[1]

^[1] Moscow State University ~ Soil Science ~ Moscow ~ Russian Federation

Paleocryogenic soil complexes were studied on gentle slopes 200 km east of Moscow. Ancient microrelief is now completely buried under agrogenically smoothed soil surface, but the sign of temperature differences between soils with different profiles is the same as it used to be long time ago, when these soils occupied different topographical positions. Lowest temperatures are typical for soils with low bulk density and high carbon content located in the areas of now buried paleomicrodepressions. Mathematical modeling proved that observed variability of soil properties is sufficient to explain lateral heterogeneity of soil temperature. Heterogeneity of soil temperature is accompanied by heterogeneity of soil moisture contents, which also resembles relict features: melted waters and rainwater are redistributed within the studied complexes in the direction of former microdepressions. And this lateral redistribution is also governed rather by internal factor, that is, lateral heterogeneity of soil properties than the external one, that is, microtopography of soil surface. It looks like there was a changeover of key factors governing the functioning of studied complexes: microtopography was the initial factor of lateral differentiation, but now this differentiation is supported by differences in soil properties. Positive feedbacks in “properties-functioning” chain are the slower rate of carbon decomposition within the areas rich in humus and lateral redistribution of carbon with melted waters. Mathematical modeling suggests that lateral transport is more important for preserving lateral heterogeneity in carbon content, and differences in decomposition rates have greater effect on the total amount of carbon stored in the system.

GEOARCHAEOLOGICAL AND PEDOSTRATIGRAPHIC STUDY OF THE SAN MICHELE CAVE OF SARACENA, CALABRIA, SOUTHERN ITALY: RECONSTRUCTION OF LATE PLEISTOCENE TO MID-HOLOCENE PALEOENVIRONMENTAL CHANGES

Pelle Teresa^[1], Scarciglia Fabio^{*[1]}, Natali Elena^[2], Tiné Vincenzo^[2]

^[1]Università della Calabria ~ Dipartimento di Scienze della Terra ~ Arcavacata di Rende (CS) ~ Italy ^[2]Soprintendenza Speciale ~ Museo Nazionale Preistorico Etnografico "L. Pigorini" ~ Roma ~ Italy

The San Michele Cave is an open hypogeal karst landform shaped in the dolostone-limestone bedrock of the Pollino Massif close to Saracena, in north Calabria (southern Italy). It was repeatedly settled and abandoned by men since Palaeolithic to Early Bronze Age. We focused on reconstruction of late Pleistocene to mid-Holocene paleoenvironmental changes recorded in the pedosedimentary infilling of the cave. We applied a multidisciplinary approach, based on geomorphological, pedological, geochemical and micromorphological analyses. Various stages of geomorphic stability and pedogenesis (with dominant humus accumulation, carbonate leaching and reprecipitation) alternated with sedimentary phases, which mainly emplaced thin-layered, (sandy-)loam deposits, with occasional very coarse debris related to rock-fall processes from the roof. Also important reworking processes from outside and/or inside the cave are evidenced by siliciclastic sediments, pedorelicts and/or papules, easily detected at the microscale in soil thin sections. Chronological constraints, obtained on the basis of archaeological findings and radiocarbon dates of charcoal fragments at different stratigraphic heights, permitted us to estimate approximate rates of sedimentary aggradation and soil formation. Moreover, the main soil features (e.g. CaCO₃ concretions, clay coatings or papules) and pedogenic iron indices were interpreted as indicators of the local response of pedogenetic processes, weathering degree and geomorphic dynamics to climatic changes, which presumably also interacted with effects of human activities both in the cave and in the surrounding external environment.

S01.01-P -13

IMPACT OF ANTHROPEDOGENESIS ON TERRACED LANDSCAPES IN THE VALBELLUNA VALLEY (VENETO REGION, ITALY)

Ferrarini Andrea^{*[1]}, Zilioli Diana Maria^[1], Bini Claudio^[1]

^[1]University of Venice ~ Department of Environmental Sciences ~ Venice ~ Italy

Man, with his activities, is currently considered the sixth factor of pedogenesis. Terracing is an ancient agrotechnical practice diffused in mountain areas, which created new anthropic landforms and anthropogenic soils. The objective of this study was to identify the impact of terracing on soil dynamic properties, and the related anthropogenic processes. The study area is located in the Valbelluna valley (Veneto, Italy), on the edge of the "Dolomites National Park". The soil survey concerned three terraced areas and one untterraced slope as term of comparing anthropic/natural soil properties. The anthropogenic soils analysed (Technic-Alloic Regosols (Escalic, Transportic, Skeletic)) showed a clear process of entisolization, with ^Ap-^C profile, the presence of Human-Transported Natural Materials (pebbles and earthy material as new parent material), artifacts, a coarser texture, a lower bulk density, C.E.C. and AWC, and a homogenization of organic carbon and carbonates along the profile. A correlation analysis between properties of natural and anthropogenic soils was, finally, made. The 56% of Pearson Coefficients, (ri), calculated for terraced soils, are significantly different in comparison to natural soils. If we take in consideration ri calculated between soil depth and each soil parameter, then the 80% of coefficients for terraced soils statistically differs ($p < 0,05$) from natural ones. The result of entisolization is a clear increase of disorder and entropy in the terraced systems, with a decreasing correlation between terraced soil properties in comparison to natural soils. The human impact determined an interruption of the anisotropic trend of soil evolution, making soil simpler (haploidization).

**INTERPRETING THE ASH PROFILE ALONG OMBROTROPHIC BOG PROFILES:
ATMOSPHERIC DUST DEPOSITIONS VS. MINERALIZATION PROCESSES**

Zaccone Claudio*^[1], Pabst Sonja^[2], Miano Teodoro M.^[3], Shotyk William^[4]

^[1]University of Foggia ~ Department of Agro-Environmental Sciences, Chemistry and Plant Protection ~ Foggia ~ Italy

^[2]University of Heidelberg ~ Institute of Earth Sciences ~ Heidelberg ~ Germany ^[3]University of Bari ~ Department of Biology and Chemistry of Agro-Forestry and Environment ~ Bari ~ Italy ^[4]University of Alberta ~ Department of Renewable Resources ~ Edmonton ~ Canada

Since the pioneering studies of Mattson and Koutler-Andersson (1954), peat cores from ombrotrophic bogs have increasingly been recognized as valuable archives of atmospheric dust particles such as minerals and amorphous materials derived from soils, and volcanic ash shards. The longest continuous record of atmospheric dust deposition in continental Europe has been provided by Etang de la Gruere (EGr), an ombrotrophic bog in the Jura Mountains of Switzerland, where 6.5 m of peat has accumulated during the past ca. 15,000 years. Recently, some authors argued that ash peaks along the EGr peat bog profiles are signs of previous periods of higher peat decomposition rather than an indication of periods of elevated dust inputs. Analyzing both the ash and the acid-insoluble ash (AIA) fraction along EGr cores, it is possible to observe that most of inorganic solids supplied to the EGr bog (i.e., 23-86%, mean 49%) consisted of atmospheric soil dusts derived from the weathering of crustal rocks. Thus, these ash peaks could not have been caused exclusively by processes such as organic matter decay, but they are either the result of an increase in the rate of supply of dust particles, changes in the rates of peat accumulation or both. Given the variation in dust deposition rates recorded since the Late Glacial, attributing peaks in ash content exclusively to variations in peat decomposition and humification seems to be a questionable, if not dangerous, practice.

IS THE CHERNOZEM SOIL RELIC OF STEPPE VEGETATION?

Vyslouzilova Barbora^{*[1]}, Schwartz Dominique^[1], Ertlen Damien^[1], Sefrna Ludek^[2], Dreslerova Dagmar^[3]

^[1]University of Strasbourg ~ Laboratoire Image, Ville, Environnement ~ Strasbourg ~ France ^[2]Charles University in Prague ~ Faculty of Sciences ~ Prague ~ Czech Republic ^[3]Academy of Sciences of the Czech Republic ~ Institute of Archeology ~ Prague ~ Czech Republic

Chernozems and luvisols are the soil types developed on loess which are widely represented in Central Europe. Traditionally it is considered that the evolution of chernozems is connected to the open landscape with grassy steppe vegetation, by contrast luvisols are supposed to be developed under forests. However, Holocene chernozems have developed in the areas where the climate is favorable to the existence of forests. This fact is to be studied in order to understand the pedogenesis of these soil types. The main focus is to see which environmental conditions in Holocene lead to the evolution of chernozems. The properties of the soil before the Neolithic age were for sure different from the recent ones. Pedogenesis circumstances, the paleovegetation before all, are reconstructed by studying buried soils. The soil organic matter is analyzed by the near infrared spectroscopy (NIRS) in order to identify the types of ecosystems which successively occupied the soils. The C14 analysis is proceed to determinate the age of soil organic matter. The charcoal is extracted from soil and identified in order to see the forest disappearance

LATE HOLOCENE ENVIRONMENTAL CHANGE IN TEOTIHUACAN, MEXICO, BASED ON A POLYGENETIC PALEOSOL

Sanchez Serafin^{*[1]}, Solleiro-Rebolledo Elizabeth^[3], Sedov Sergey^[4], Mcclung Emily^[2]

^[1]Posgrado en Ciencias de la Tierra, UNAM ~ Edafología ~ Mexico ~ Mexico ^[2]Instituto de Investigaciones Antropológicas UNAM ~ Arqueología ~ Mexico ~ Mexico ^[3]Institute of Geology, UNAM ~ Edafología ~ Mexico ~ Mexico

^[4]Institute of Geology, UNAM ~ Edafología ~ Mexico ~ Mexico

Teotihuacan was one of the largest settlements of ancient Mexico, known for hosting one of the greatest pre-Hispanic urban civilizations, which flourished in the interval I-VII centuries A.D., reaching an extension of approximately 20 km² and 125,000 inhabitants. Soil is very important for the cultural development as it is part of the natural environment, the base of natural ecosystems as well as agriculture. This research focuses on a polygenetic paleosol in Teotihuacan that was identified as the soil cover during the time of settlement. The date obtained from soil organic matter from a buried AE horizon was 2 060 +/- 40 14C BP representing its minimum age. The paleosol is very well developed, with AE, AB, BCK horizons. The features of the horizons are the results of different stages of pedogenesis: AB horizon is dark, with strong vertic features (angular blocks, stress cutans, hard consistence), indicating seasonal climate; micromorphology shows illuvial clay in fractures, representing an increase of the humidity, which is identified by the Fe nodule, and illuvial clay in pale AE horizon. In this horizon there are also agrocultans, charcoal fragments and crust fragments indicating irrigation during cultivation. BCK horizon has also illuvial clay on carbonates, showing a previous dry phase.

PALEOENVIRONMENTAL IMPLICATIONS THROUGH THE STUDY OF AN EEMIAN PALEOSOL IN NORTHWESTERN SARDINIA (ITALY)

Zucca Claudio*^[1], Andreucci Stefano^[2], Shaddad Sameh^[1], Madrau Sameh^[1], Pascucci Vincenzo^[2], Kapur Selim^[3]

^[1]University of Sassari ~ Dep. of Territorial Engineering ~ Sassari ~ Italy ^[2]Università di Sassari ~ Dipartimento di Scienze Botaniche, Ecologiche e Geologiche ~ Sassari ~ Italy ^[3]University of Çukurova ~ Departments of Soil Science and Archaeometry ~ Adana ~ Turkey

Sardinia is one of the main islands of the Mediterranean Sea where it occupies a central position. The Island has been considered tectonically stable since the last 2My and, therefore represents a key area to perform studies on climate and paleoenvironmental changes that have occurred during the Quaternary. Several studies conducted along the NW coast of the island have documented and precisely dated, by the Optically Luminescence Technique, a quasi continuous succession of sandy deposits (aeolian and shallow marine) referred to MIS5; in particular the substages MIS5e and 5c. Most of these deposits are interlayered with soils. The aim of this work is to define the paleoenvironmental changes related to a soil belonging to the studied succession, by means of an in-depth micromorphological study. In particular, the presence of this paleosol is associated to the fast climatic fluctuations that took place between MIS5e and MIS5c. Three main phases were highlighted. A wet period, with intense carbonate leaching, was followed by the establishment of very dry conditions and by the formation of a thick calcrete horizon. Finally, a warm and wet phase lead to the rapid weathering of the calcrete top layer and to the formation of reddish horizons showing moderate pedogenic development.

PEREGLACIAL FEATURES IN SOILS IN THE NORTH OF EUROPEAN RUSSIA

Pogozhev Evgeniy^{*[1]}, Zavarzina Anna^[1]

^[1]Faculty of Soil Science Lomonosov Moscow State University ~ General pedology ~ Moscow ~ Russian Federation

The primary minerals of coarse particle-size fractions comprise the bulk of the soil matrix. The specificity of their disintegration and weathering are important for the neoformation of secondary mineral phases, development of soil structure and chemical properties. The mineralogical composition of coarse fractions (1-0.01 mm) has been studied in the profiles of podzolic soils and podzols which developed on deposits of Valdai glaciation in the Kenozero National Park (Arkhangelsk region, Russia). The key plots were located in the area of geochemical junction of mixed moraines of Fennoscandian and Ural glaciations. The soils were quite rich by heavy minerals (2-17% by weight) that were mainly represented by hornblende, epidote and garnet. The distribution of primary minerals in the fractions of different particle-size fractions in all studied profiles was largely the result of minerals stability to mechanical disintegration. Quartz was the most stable mineral, grains of feldspars and hydrated biotite were easily broken down into smaller particles and concentrated in 0.05-0.01 mm size fraction. Epidote and garnet were characterized by relatively high physical and chemical stability in comparison with hornblende, which underwent intensive disintegration and weathering in the studied soils. Based on minerals distribution in the size fractions and surface morphology of the grains a following set of minerals stability in the soils of the middle taiga zone was done: quartz>garnets> epidote >feldspars>amphiboles(hornblende)>hydrated biotite. The specific morphological feature of the podzolised soils of the studied area was weakly pronounced by eluvial processes leading to weak color differentiation of these soils.

RECENT STUDIES OF HISTORICAL AND CONTEMPORARY FIRES FROM ESTONIAN PEAT BOG PROFILES

Sillasoo Ülle^{*[1]}, Soots Merle^[1], Pensa Margus^[1]

^[1]Tallinn University ~ Institute of Ecology ~ Tallinn ~ Estonia

Studies on past climate changes from peat bog profiles have introduced newly the topic of palaeofires, since this is one of the possible source of errors when interpreting palaeohydrological records from boreal bogs. Many changes in past microtopes and their hydrological conditions inferred from plant macrofossil composition of peat can be related to the presence macroscopic charcoal in adjacent layers as the evidence of fires. The results of three case studies will be presented from bogs in Estonia: Männikjärve, Selisoo and Veskisoo. In first two bogs, 4.5 m cores were studied for plant macrofossils and charcoal, one core from each bog. In the third bog, a transect of five 35 cm top peat profiles was analysed. As for Männikjärve and Selisoo bog (NE Estonia), there is to do with a complex raised bog type with hummocks, hollows and pools. Veskisoo bog (N Estonia), instead, belongs to a non-complex Calluna-predominating bog type, near a lake in the region of extended Pinus forests on sandy soils with very high fire susceptibility. Long and short term fire histories (c. 4000 and 100 years, respectively) and changes in vegetation preceding and following fires are studied and compared. We argue that fire frequency in bogs depends on the surrounding vegetation; that shrub communities both cause and result from bog fires; and that in the lowened microtopes, the best conditions appear for dissemination of wider range of bog plant species post fire.

SHORT TIME DEVELOPMENT OF TECHNOSOLS IN MINING ENVIRONMENT

Joussein Emmanuel^{*[1]}, Marilyne Soubrand^[1], Laurent Caner^[2]

^[1]Université de Limoges ~ GRESE ~ Limoges ~ France ^[2]Université de Poitiers ~ HydrASA ~ Poitiers ~ France

Soils developed from human-made substrates are of interest due to the increase of the anthropogenic activities. These soils are classically designate as technosols, (i) result generally from potentially contaminated materials, (ii) are mainly characterised by anthropogenic parent material of organic and mineral nature which origin can be either natural or technogenic. Moreover, the increasing number of sites affected by anthropogenic materials is important, and their impact on the environment is effective for plants and water resources. From these purposes, technosols require an understanding of their functioning and evolution. The aim of this study is to understanding the pedogenesis of young Technosols mine developed from a old gold mine settling basin abandoned since 1960. Wastes are highly contaminated in metals and metalloids (Pb, As and Sb). Technosols are naturally developed on it and accompanied by native vegetation. Results show clearly the soils development from short time range (40 years). Briefly, soils are weakly thick (up to 15 cm), acid with a little CEC. Geochemical behavior of various horizons is to a great extent similar between them but quite different to that of parental material. Clay minerals XRD investigations evidenced the formation of smectite in the upper horizons in a short time. Results has to be taken as an indication of a low degree of evolution of these young technosols, as already shown in the case of young volcanic soils (e.g. andosols). Discussion will be realised toward soil pedogenesis, mineralogical way (As, Sb, Pb-bearing phases, clay minerals) and physical chemical properties.

SOILS, VEGETATION AND CLIMATE OF THE PENULTIMATE INTERGLACIAL (MOIS 7) IN UPLANDS TO THE NORTH OF THE CARPATHIANS

Lanczont Maria^{*[1]}, Komar Maryna^[3], Bogucki Andrij^[4], Madeyska Teresa^[5]

^[1]Maria Curie-Skłodowska University ~ Department of Geoecology and Palaeogeography ~ Lublin ~ Poland ^[2]Polish Academy of Sciences ~ Institute of Geological Sciences ~ Warszawa ~ Poland ^[3]National Academy of Sciences of Ukraine ~ Institute of Geological Sciences ~ Kyiv ~ Ukraine ^[4]Ivan Franko National University ~ Department of Geomorphology and Palaeogeography ~ Lviv ~ Ukraine ^[5]Polish Academy of Sciences ~ Institute of Geological Sciences ~ Warszawa ~ Poland

Discussion whether the climate warming correlated with the MOIS 7 should be defined as cold interglacial or warm interstadial has lasted for years. In loess profiles located in 49-51°N parallel zone between 20°E and 35°E (southern Poland, north-western and central Ukraine), palaeosols occur between loess beds corresponding to the Odra and Warta glaciations. These are sets of two superimposed paleosols. In the western part of the area these soils are mainly of luvisol type in central one, the upper paleosol is podzolic chernozem, and lower - luvisol or cambisol. In the eastern part, both paleosols are chernozems. Pollen analysis of older soils indicates the plant succession from open country vegetation with spruce to loose pine-birch mixed forests. During the climate optimum, these mixed forests contained also oak, hornbeam, elm and shrubs in the western and central part of the area. In an eastward direction the number of trees was lower, and forests were replaced by forest-steppe or even steppe vegetation. The successive cooling is evidenced by the predominance of herb communities. Then forest-steppe communities developed, with an admixture of pine, birch and not numerous thermophilous trees. Both the character of paleosols and vegetation indicate that the discussed period can be defined as cold interglacial composed of two warmer periods. They were separated by the climate cooling when loess accumulation and/or slope processes were often active. The older warming was more humid and the younger one more dry. Continentality of climate increased in an eastward direction in the whole penultimate interglacial.

SPECTRA OF GRAIN SIZE DISTRIBUTION OF PEDOARCHIVES AS AN INDICATOR FOR CULTURAL LANDSCAPE DEVELOPMENT: THE NEOLITHIC BURIAL MOUND KÖNIGSGRAB (SACHSEN-ANHALT, GERMANY)

Khamnueva Svetlana V.^{*,[2]}, Mitusov Andrey V.^[2], Bork Hans-Rudolf^[2]

^[1]University of Kiel ~ Institute for Ecosystem Research and Geoarchaeology ~ Kiel ~ Germany ^[2]University of Kiel ~ Institute for Ecosystem Research ~ Kiel ~ Germany

Buried soils and sediments (archaeosediments, colluvium, etc.) with traces of soil formation are defined as pedoarchives. They preserve information about evolution and transformation of soils and cultural landscapes. Spectra of grain size distribution (GSD) of pedoarchives, obtained by laser diffraction, are useful indicators for these processes, although methodological aspects of their application are not well developed. In present research, GSD of the embankment and modern soils was analyzed to identify mineral inputs, estimate stocks and accumulation rates of silt and sand, to identify sources of the material composing the embankment, and to relate GSD variation with land use changes. The embankment consisted of three phases: phase I (before 3650 BC), phase II (after 3650 BC) and phase III (after 3100-2700 BC). Modern soil, approximately 75 years old, has developed on the surface of the embankment and in its surrounding. GSD of modern soil horizons indicated erosional input of coarse sand and aeolian input of silt in the size range 26.3-62.5 μm . GSD of phase I showed that this material represented the remnants of Pleistocene soil, which was preserved due to specific landscape position and human activity. GSD variation within phase II pointed at aeolian accumulation of silt during its exposition. GSD of phase III suggested that deeper subsoil layers were used for its construction, implying that erosion occurred in the area approximately in the period between phases II and III. Therefore, GSD provided new information about the materials composing burial mound, about the initial state and transformation of palaeolandscapes' soils.

STUDY WITH N AND K FERTILIZATION OF SUGARCANE RATOONS HARVESTED WITHOUT BURNING

Dias Fábio Luis Ferreira^{*[1]}, Rossetto Raffaella^[1], Cantarella Heitor^[1], Tavares Silvio^[1], Vitti André Cesar^[1]

^[1]Agência Paulista de Tecnologia dos Agronegócios ~ Departamento de Descentralização do Desenvolvimento ~ Piracicaba ~ Brazil

The harvest without burning , leaves on the soil a great amount of residues that as in other cultures protect the soil and recycle nutrients. This new condition of handling of the culture demands adjustments mainly in what concerns the more productive current varieties, also demanding more from the soil system. This way the aim is to study the answer curve of the sugarcane ratoon to the nutrients N and K in cultivation areas without burning in the third, fourth and fifth cut. The experiments were planted in factorial design with 16 treatments - four doses of nitrogen (0; 60; 120 and 180 kg/ha of N) and four potassium doses (0; 70; 140 and 210 kg/ha of K₂O) placed in randomized blocks with four replications. The portions with 75m² each. The obtained results on these three years of handling, allow to conclude that there was significant answer at the productivity due to the manuring with nitrogen and potassium. All the doses were economically profitable and doses between 120 and 140 kg/ha of the N and K were respectively more sustainable.

THE EFFECT OF WOOD ASH FERTILIZATION ON SOIL CHEMICAL PROPERTIES AND GREENHOUSE GAS (GHG) EMISSIONS IN BOREAL PEATLAND FORESTS

Maljanen Marja^{*[1]}, Liimatainen Maarit^[1], Martikainen Pertti J^[1], Hytönen Jyrki^[1]

^[1]University of Eastern Finland ~ Environmental Science ~ Kuopio ~ Finland

The use of energy wood harvested from forests is increasing rapidly in Finland and consequently larger amounts of wood ash is produced annually in power plants. As wood ash is alkaline and contains all the elements required for plant growth, except nitrogen, it can be utilized as fertilizer in forestry, especially in boreal peatland forests, which are naturally rich in nitrogen. The long-lasting effects of wood ash on the nutrient status and growth of conifers growing on peatlands have been reported in many studies. The use of ash excessively rich in cadmium and other heavy metals has been restricted in forestry. Improved nutrient availability and increase in soil pH can increase microbial activity and GHG emissions from ash fertilized soil. We studied the effect of wood ash fertilization on soil chemical properties, N₂O/CH₄ fluxes and ecosystem/soil respiration rates in three boreal peatland forests in Western Finland. Two of the sites were fertilized eight years before and one in the beginning of this two year- study. In addition to the field measurements, laboratory incubations were done to study the effect of variable ash doses on soil chemical properties and N₂O and CO₂ production rates. Ash addition increased e.g. soil electrical conductivity, SO₄²⁻ and PO₄³⁻ concentration, but it did not significantly change soil pH. Preliminary results show only minor effects on N₂O and CH₄ fluxes in situ but ash fertilization increased soil respiration at one site. Thus, wood ash application had minor effects on GHG fluxes even soil chemical properties were changed.

TUBULAR CALCRETES. MORPHOLOGY AND GENESIS OF A NEW TYPE OF CARBONATE ACCUMULATION FOUND IN SOUTHWESTERN URUGUAY

Morrás Héctor J. M.^{*[1]}, Tófaló Ofelia Rita^[2], Sánchez Betucci Leda^[3]

^[1]INTA - Centro de Investigación de Recursos Naturales ~ Instituto de Suelos ~ Castelar ~ Argentina ^[2]UBA-Facultad de Ciencias Exactas y Naturales ~ Departamento de Ciencias Geológicas ~ 1428 Buenos Aires ~ Argentina ^[3]Universidad de la República ~ Departamento de Geología y Paleontología ~ Montevideo ~ Uruguay

The Fray Bentos Formation, an Oligocene-Early Miocene calcareous loess-like silt deposit with paleosols and diverse pedogenic calcretes outcrops in southwestern Uruguay. A new type of tubular calcareous accumulation, apparently not referred by other authors, is here described. These calcretes consist of hard calcareous tubular units containing the silty groundmass in their cylindrical central part; the transversal section of the tubes is circular or pseudo-hexagonal about 10-30 cm in diameter and their vertical length is about 80-130 cm. These tubes are juxtaposed, frequently displaying a diagonal orientation, the whole developing horizontal levels with undulated upper and lower limits; two levels of these tubular structures are usually superposed, the vertical development of the calcrete thus reaching up to 350 cm. Observations made on exposed surfaces of the calcrete showed a circular or pseudo-hexagonal microrelief, about 300 cm in diameter, with a 20-30 cm difference in height between the microcrests and the center of the depressions. Several morphological features of this carbonate accumulation –particularly an upper limit related to a normal gilgai microrelief and tubular units deviated from the vertical related to deep cracks and argilliturbation- together with the mineralogical nature of the sediment suggest a previous development of Vertisols. The tubes are thus interpreted as calcareous infillings due to the carbonate solubilization from overlying deposits, thus fossilizing a fissure pattern of a pedogenic paleosurface. The paleoclimatic implications of these original pedogenic calcretes are discussed.

ZINC UPTAKE EVALUATION BY MAIZE PLANT AND DETERMINATION OF CRITICAL LEVEL IN CALCAREOUS SOILS OF IRAN

Sepahvand Haniyeh^[2]

^[1]university of guilan ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of ^[2]university of guilan ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of

From the main families of calcareous soils , 25 points studied for determination of Zinc critical level and evaluation of zinc fertilizations effects on maize uptake with the goal of supply better nutrition conditions and balanced application of chemical fertilizers in this province. The main families of soils were Loam and clay-loam and in Inceptisol series. The pH of the soils obtained in the range of 7.5-8 and available Zn obtained at the range of 0.01-2.05 mg kg⁻¹. pot experiment of Singel Crass 704 maize plant was done in the complete randomized design with three replications and two treat of zero and zinc (20 ppm) and irrigation with distilled water. After harvesting, the zinc uptake and the amount of zinc in maizes were measured by dry ashing method. The average amount of zinc by maizes was 28.71 mg kg⁻¹ in blank treats and 84.02 in fertilized treats. The amounts of zinc uptake also obtained 49.8 in blank treats and 110.8 µg g⁻¹ of plant in fertilized traets. The critical level of zinc obtained 0.37 mg kg⁻¹ by Cate-Nelson method.

BIOGEOCHEMISTRY OF METALS IN RIVER FLOODPLAINS AND CONSEQUENCES FOR BIOAVAILABILITY FOR PLANTS AND SOIL ORGANISMS

Van Der Zee Sjoerd*^[1]

^[1]Wageningen University ~ Ecohydrology ~ Wageningen ~ Netherlands

Dutch river floodplains are, just as in many other countries, contaminated with metals. Usually, contamination levels for heavy metals are such that interactions with the solid soil phase is predominantly in the form of sorption, rather than chemical precipitation. The biogeochemistry of heavy metals, and others such as Al, Fe, and Mn, is strongly affected by the seasonal sequence of droughts and flooding and the associated redox potential Eh changes. However, depending on soil properties, such seasonal changes cannot always be simply translated into those of Eh. In a field scale experimental monitoring effort in combination with advance modeling, it was possible to show quite good agreement between measured and modeled heavy metals' concentrations in soil solution. More importantly, it revealed important and not yet understood discrepancies for certain components such as Pb and As. Considering bioavailability of different metals for plants and ecosystems, usually at non-lethal levels, reveal that aerenchymic wetland plants may react quite differently from others that require aerobicity in the root zone. Heavy metal uptake by soil organisms such as nematodes, which are often considered to well represent soil health, may be described with relatively simple models. Alternatively, experimental research on uptake by Collembola requires assays that must be well thought through, to avoid artefacts. Some gaps in experimental data that are perceived as critical are identified in this presentation.

CARBON DYNAMICS IN SOIL AND FINE ROOT BIOMASS OF RIPARIAN FORESTS

Rieger Isaak^[2], Kowarik Ingo^[2], Cierjacks Arne^[2]

^[1]Technical University of Berlin ~ Departement of Ecology, Ecosystem science / Plant Ecology ~ Berlin ~ Germany

^[2]Technical University of Berlin ~ Departement of Ecology, Ecosystem Science / Plant Ecology ~ Berlin ~ Germany

Riparian forests are characterized by high organic carbon stocks in soil and vegetation. At the same time, floodplain ecosystems are subjected to human alterations such as dike construction which may have profound impact on carbon cycling. In this study, we studied historic and current carbon dynamics in river sediments and fine root biomass of riparian forests in Donau-Auen National Park, Austria. Overall, 96 trees of four dominant tree species and adjacent soils were sampled for dendrochronologic and dendrogeomorphologic analyses along a lateral gradient from the Danube main channel at both sides of the Marchfeld dike. Tree age and depth of the stem base below ground were used to estimate historic carbon sedimentation rate. Actual sedimentation rate was determined in 48 sediment traps. In addition, we measured the carbon pool of fine root biomass in soil samples and carbon growth rate of fine root biomass using ingrowth cores. First results indicate that historic sedimentation rates of organic carbon significantly decreased with greater distance from the next river channel. Moreover, historic annual carbon sedimentation rates of soil in inactive floodplain ($1.5 \text{ t ha}^{-1} \text{ a}^{-1}$) areas were significant lower than in active floodplain forests ($2.9 \text{ t ha}^{-1} \text{ a}^{-1}$). Also, current carbon pool of fine root biomass in inactive floodplain (3.6 t ha^{-1}) was significant lower than in active floodplain (6.5 t ha^{-1}). Our study highlights the role of river dynamics for soil and fine root carbon accumulation as dike construction proved to reduce allochthonous carbon input through sedimentation and fine root biomass.

CATEGORIZING BASIC FACTORS DRIVING SOIL GENESIS, PEDOVARIABILITY AND PLANT ASSEMBLAGES IN MEDITERRANEAN TEMPORARY WETLANDS (TWS)

Capra Gian Franco^[1], Caria Maria Carmela^[1], Buondonno Andrea^[2], Seddaiu Giovanna^[3], Vacca Sergio^[1], Bagella Simonetta^[1]

^[1]Università di Sassari ~ Dipartimento di Scienze Botaniche, Ecologiche e Geologiche ~ Nuoro ~ Italy ^[2]Seconda Università di Napoli ~ Dipartimento di Scienze Ambientali ~ Caserta ~ Italy ^[3]Università di Sassari ~ Dipartimento di Scienze Agronomiche e Genetica Vegetale Agraria ~ Sassari ~ Italy

A research was carried out in six Temporary Wetlands (TWs), located in north-western Sardinia (Italy), with the aim to categorize the basic factors driving and linking soil genesis and plant assemblages in Mediterranean basin. In order to satisfy such purpose the main hydrologic parameters as well as soil properties, pedogenic features and vegetation patterns were deeply investigated. Within each TW a central (CB, located on the toe slope), intermediate (IB, on foot/back slope), and outer (OB, on summit) belt was recognized. Soil morphology and pedovariability changed clearly along each OB/IB/CB transect, highlighting evidence of a distinctive soil micro-catena, i.e. from the poorly developed Entisols at the summit to the more evolved Alfisols at the toe slope. Indeed, CB and OB were very clearly defined pedo-environments, with soils belonging either to strongly developed Alfisols or poorly evolved Entisols, respectively, while, the IB seems represents a sort of pedo-transitional environment from OB to CB. The statistical analyses (ANOVA and ANOSIM) performed on the investigated soil physical-chemical parameters showed no significant differences between belts. On the opposite, the ANOSIM analyses of the contribution of each plant species to vegetation cover showed significant differences between belts. The overall correlation (managed by PCA), of the investigated parameters, i.e. topography, hydrology, soils and vegetation reasonably indicates that the combined effect of topography and hydrology acted as primary factors governing soil and vegetation in a complex relationships/feed-backs network, thus combining soil evolution and the subsequent vegetation assemblage, and finally determining belt differentiation.

S01.02-P -4

DRAINAGE EFFECTS ON LABILE ORGANIC CARBON FRACTION IN TOPSOIL OF PEATLANDS

Kalisz Barbara^{*[1]}, Lachacz Andrzej^[1], Glazewski Roman^[2], Pozniak Pawel^[1]

^[1]University of Warmia and Mazury ~ Soil Science and Soil Protection ~ Olsztyn ~ Poland ^[2]University of Warmia and Mazury in Olsztyn ~ Environment Protection Engineering ~ Olsztyn ~ Poland

Labile organic carbon compounds are easily oxidizable and degradable, i.e. are cycling up to several years in the environment. One of labile organic carbon compounds is carbon extracted with hot and cold water. Water-extractable organic carbon fractions contain a wide spectrum of organic compounds such as aminoacids, saccharides, aminosugars and hemicelluloses. Although it does not include complete labile fraction (only water-soluble organic compounds) it is a good indicator of organic matter quality as it corresponds with microbial biomass, total organic carbon and carbon dissolved in peatland waters. Hot and cold water-extractable organic carbon fractions were analysed in field moist and air-dried soil samples taken from topsoils of peatland drained 150 years ago. As all organic soils after drainage, the peatland had undergone the process of organic matter transformation, known as muck-forming process. During this process, intense mineralization and secondary humification of organic matter took place. The contents of cold and hot water-extractable organic carbon fractions did not exceed 1% and were correlated with total organic carbon. The amount of water-soluble organic compounds was higher in air-dried samples than in field moist soil samples. The obtained results confirmed earlier studies that although water-extractable carbon accounts for a small part of organic matter, it is a good indicator of changes.

HIGH-RESOLUTION MONITORING OF THE AIR- AND WATER BALANCE IN A CALCARIC GLEYSOL OF THE MARSH IN SCHLESWIG-HOLSTEIN, NORTHERN GERMANY

Dorau Kristof^[1]

^[1]University of Cologne ~ Department of Geosciences ~ Cologne ~ Germany

The interactions between the atmo-, hydro-, bio- and pedosphere affect the dynamics of the air- and water balance in soils at a small temporal and spatial scale. Because of high costs there are only few high-resolution measurements. This study was conducted to identify the key-processes of water balance and movement in the marsh of Schleswig-Holstein, Northern Germany. With HYDRUS-1D a soil hydraulic model was parameterized and validated. For this purpose, some meteorological parameters, soil matric potential and water table depth were recorded hourly in a non-cultivated calcaric Gleysol developed from marine sediments from April 2010 to March 2011. Matric potential was measured in 10, 20, 30, 60, 100 and 150 cm depth with newly constructed pF-meter and converted to water contents using van Genuchten equation. Our results show that besides seasonal changes in water content specific event (movement of wetting front after rainfall event) and cyclic processes (scheme of capillary rise due to diurnal temperature differences) takes place. High reference evapotranspiration (711 mm) results in capillary rise from shallow groundwater which causes strong annual variations from 5 cm to below 200 cm water table depth. However, it can be seen that in dry years plant available water is sufficient within the profile but oxygen is the limiting factor for plant growth. With a Nash-Sutcliffe coefficient ranging from 0.82 in 10 cm depth to 0.99 in 150 cm depth the model was successfully applied. Hence, HYDRUS-1D can be used at sites with high groundwater dynamic to predict water- and air balance.

HOT ZONES OF SOIL NITROGEN CYCLING IN FLOODPLAINS OF A PERIALPINE RIVER

Shrestha Juna^[1], Luster Joerg^{*[1]}, Huber Benjamin^[1], Niklaus Pascal A.^[2], Frossard Emmanuel^[3], Tockner Klement^[4]

^[1]Swiss Federal Research Institute WSL ~ Forest Soils and Biogeochemistry ~ Birmensdorf ~ Switzerland ^[2]University of Zurich ~ Institute of Evolutionary Biology and Environmental Studies ~ Zurich ~ Switzerland ^[3]Swiss Federal Institute of Technology ETH ~ Institute of Agricultural Sciences ~ Zurich ~ Switzerland ^[4]Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB) ~ na ~ Berlin ~ Germany

Evaluating ecosystem services of river floodplains such as provision of drinking water and climate regulation needs to consider soil properties and processes. Although many studies have addressed denitrification in floodplain soils, comprehensive assessments of nitrogen cycling are rare. The floodplains of the perialpine Thur River in NE Switzerland are characterized by a flood pulse regime with short floodings and long base-flow conditions during which soils are mostly unsaturated. We characterized N pools, transformation rates and fluxes in soils of different parts of adjacent channelized and restored river sections. The results revealed two zones within the restored section with often increased N cycling when compared to the rest of the floodplain: (i) an alluvial forest where fine soil texture probably favors the preservation of anaerobic conditions in micro sites during generally unsaturated conditions, and (ii) a gravel bar zone characterized by frequent flood disturbance with high sediment deposition. Here, deposition of unstructured sediments and litter production linked to a flooding event appear to be responsible for temporary increases in available organic matter which in turn trigger an acceleration of N turnover. As a consequence of this and of a large small-scale heterogeneity in terms of geomorphology, soil properties and environmental conditions, concurrent hot spots of mineralisation, nitrification and denitrification (including related N₂O efflux) can occur. With respect to their filter function, our results emphasize that nutrient rich floodplain soils which are unsaturated most of the times have to be considered both a sink and a source of potentially harmful nitrogen species.

IMPACT OF RIVER RESTORATION ON CARBON STORAGE IN SWISS FLOODPLAINS

Bullinger-Weber Geraldine^[1], Renée-Claire Le Bayon^[2], Aurélie Thebault^[3], Eric Verrecchia^[1], Claire Guenat^[3]

^[1]UNIL ~ Geology-paleontology ~ Lausanne ~ Switzerland ^[2]UNINE ~ Biology ~ Neuchatel ~ Switzerland

^[3]ECOS~WSL~EPFL ~ Lausanne ~ Switzerland

Floodplain restoration is becoming more important worldwide and in Switzerland several projects have been implemented to maintain or recreate their ecological functions, in particular flood protections and biodiversity. At present time little is known about the potential of floodplain soils to release or to accumulate carbon that are strongly influenced by fluvial dynamics and land use. The aim of this study is to quantify and better understand carbon storage within alluvial soils according to a pedological gradient (in situ pedogenesis duration) in more or less deeply human-impacted floodplains. We hypothesize that in near-natural floodplains, this pedological gradient lead to i) an increase of organic carbon concentration and stocks in the topsoil ii) a stabilization of organic carbon in the smallest granulometric fraction (<0.25 mm). A successful river restoration should recreate such a carbon storage gradient. We tested these hypotheses using three different sites, a near-natural floodplain along the Rhine River and two restored floodplains along the Thur and Emme Rivers. Preliminary results show that in near-natural floodplain, organic carbon concentration increases along the pedological gradient. For the Emme floodplain, the same trend is noticed whilst for the Thur, no statistical difference is found among soil types composing this gradient. These different patterns can be explained by both physico-chemical pedological parameters and fluvial dynamics resulting from the river restoration characteristics (length and width of the widening).

IMPACTS OF SURFACE MINING ON PEATLAND FUNCTIONS AND RECONSTRUCTION OF NEW ECOSYSTEMS IN THE OIL SAND DEVELOPMENT AREA OF NORTHEASTERN ALBERTA.

Nwaishi Felix C.^[1], Petrone Richard M.^[1], Price Jonathan S.^[2]

^[1]Wilfrid Laurier University, Cold Regions Research Centre ~ Geography and Environmental Studies ~ Waterloo ~ Canada ^[2]University of Waterloo ~ Department of Geography and Environmental Management ~ Waterloo ~ Canada

Peatlands represent more than 45% of the landscape in northeastern Alberta, Canada. These peatlands provide vital environmental services such as carbon sequestration and water cycling within the Boreal Plain ecozone. Extraction of oil (bitumen) through surface mining forms a major disturbance to peatland ecosystems in this region and could lead to irreversible damage on the functions of these ecosystems. As the persistence of this disturbance remains certain, this study focuses on its impact on peatland ecosystem functions and the feasibility of engineering a new ecosystem in the post-mined landscapes. The vital environmental services provided by peatlands in this region and the footprints of the disturbance from oil sand extraction are discussed and major components of current research on the reconstruction of the disturbed landscapes to a functional ecosystem are highlighted. The discussion from this study presents an overview of the disturbances perpetrated by oil sand development projects, and provides preliminary information on reclamation projects being implemented by the energy sector to reduce the environmental impacts of their activities on peatland ecosystem functions.

INFORMATIVENESS OF THE COMPOSITION OF LYSIMETRIC WATER

Barsova Natalia^[1], Motuzova Galina^{*[1]}

^[1]Moscow State University ~ Faculty of Soil Science ~ Moscow ~ Russian Federation

Soil lysimetric waters are informative indicator of the status of any landscape. The results of the investigation of water of Ivankovsky reservoir, ground water and lysimetric water of soddy soils from the coastal zone have served as the evidence of the correctness of this thesis. Content of SO₄²⁻ in lysimetric water decreased in comparison with atmospheric precipitation due to their sorption by soil; of NO₃⁻ - because of their involving in biological turnover. Lysimetric waters have relatively high concentration of phosphates and potassium, mainly due to the past agricultural use of soils. Water-soluble organic substances reach ground waters in limited quantities. Concentration of trace elements in soil lysimetric water is low because of the poverty of parent rocks by them. Migration of metals in soil is limited mainly because of neutral reaction. The greatest concentration of ions Fe³⁺ is observed in lysimetric waters, because of formation of complexes with organic substances. Zinc and copper concentration in ground water is higher than in lysimetric water. It can be consequence of coastal filtration of metals from water reservoir, where their concentration often is rather high. Concentration of Ca²⁺, Mg²⁺ in water from reservoir is higher than in lysimetric water. In spring they are enriched by Na⁺, Cl⁻, SO₄²⁻, that have technogenic origin. These results have shown that lysimetric waters characterize the flows of substances which bind together atmospheric precipitation, soil solutions and ground waters.

**INVESTIGATION OF THE ENVIRONMENTAL CHANGES PRODUCED BY HUMAN ACTIVITY
ON EXAMPLES OF A SODIC LAND AND A KARST LAND**

Nyilas Tünde^{*[1]}, Imre Mariann^[2], Nagy Gábor^[3], Király András^[3], Venczel Márton^[4]

^[1]University of Szeged ~ Department of Mineralogy, Geochemistry and Petrology ~ Szeged ~ Hungary ^[2]Inspectorate for Environment, Nature and Water of Lower Tisza District ~ Department of Soil and Water Protection ~ Szeged ~ Hungary

^[3]SoilChem Agricultural and Environmental Laboratory ~ - ~ Mórahalom ~ Hungary ^[4]Museum of the Three Rivers Land ~ - ~ Oradea ~ Romania

Nowadays natural habitats are imperilled because of human landscape-transformer processes and negative effects of climate change. Watery habitats belong to the most vulnerable lands because low rate of anthropogenic effects can lead to significant and fast changes in these places. Lake Nagyszéksós (sodic lake, Mórahalom, SE Hungary) and Püspökfürdő (karst lake with thermal spring-water, Oradea, NW Romania) are two examined areas with different environmental conditions. In contrast with 'Püspökfürdő' Lake Nagyszéksós is influenced by anthropogenic effects in lower degree. Conditions of two watery habitats and anthropogenic effects in dynamics of environmental and ecological processes are examined in the project. Paleoecological analysis, soil- and water-chemical measurements and geological examinations are carried out in the areas. Based on laboratory measurements and field studies we are able to do comparative analysis and examine the evolution of the areas. Aims of our work are to classify ecological potential, to define the rate of degradation and to determine ecological function of the natural habitats. Using results of this research, numerous ecological changes can be forecasted. These forecasts can promote the development of a sustainable land use concept in case of Lake Nagyszéksós. Results give possibility to sustainable development of tourism investments and operation in case of Püspökfürdő. The international realization of the project is supported by the Hungary-Romania Cross-Border Co-operation Programme of the European Union in 'Exploration and Comparative Analysis of the Effects of Regional Climate Change at Watery Habitats' project (HURO/0901/207/2.2.2). Some measurements was supported by the Hungarian Scientific Research Found (K 81181).

LAND USE DURATION DIFFERENTIALLY AFFECTS WETLAND SOIL PRODUCTIVITY IN EAST AFRICA

Dold Christian^{*[1]}, Becker Mathias^[1], Changwony David Kipkemoi^[2], Lanyasunya Titus^[2], Kamiri Hellen^[3], Kreye Christine^[1], Schneider Dominika^[1]

^[1]University of Bonn ~ Plant Nutrition ~ Bonn ~ Germany ^[2]Kenya Agricultural Research Institute ~ Animal Production ~ Naivasha ~ Kenya ^[3]Moi University ~ School of Agriculture and Biotechnology ~ Karatina ~ Kenya

In the face of land shortages, progressing upland degradation and climate change effects, the agricultural potential of wetlands has recently been recognized in East Africa. As a result, pristine wetlands are increasingly cleared from vegetation and converted into sites of production. If production levels can be sustained is likely to depend on environmental factors, the wetland type and the land management. We assessed crop production potential and parameter changes in the solution and solid phase of wetland soils under different types (unused, grazed, cropped) and durations (0-30 years) of land use in floodplains, inland valley swamps and littoral lakesides of East Africa between 2008 and 2011. Most dramatic changes in solution phase parameters (ion exchange resins) and crop production (maize/rice/forage grass biomass in potted soil) were observed from lowland sites and in the coarse-textured soils of floodplains, starting seven years after drainage and/or use. Heavy clay soils from highland valley swamps and sites where anaerobic conditions were maintained (rice / taro) appeared to be more resilient to land use changes but also show distinct declines in total C and N pool sizes after 20-30 years of use. In the littoral region of the rift valley lakes, both maize and forage grass appeared to be affected by soil pH and EC than by land use duration. We conclude that agriculturally used wetlands differentially respond to conversion and use and that wetlands' vulnerability or resilience depends on wetland type, soil texture, and the soil aeration status.

RESTORATION OF ECOLOGICAL FUNCTIONS IN A WET MEADOW ON PEAT SOIL: A 3 YEARS POST OPERATION SURVEY IN THE ESTUARY OF SEINE RIVER (FRANCE).

Mchergui Chockri^[1], Estelle Langlois^[1], Michael Aubert^[1], Marthe Akpa-Vinceslas^[1], Aurélie Husté^[1], Pierre Margerie^[1], Sandrine Samson^[2], Fabrice Bureau^[1]

^[1]Laboratoire ECODIV ~ Seine-Maritime ~ Rouen ~ France ^[2]Service environnement du Grand Port Maritime de Rouen ~ Seine-Maritime ~ Rouen ~ France

The restoration of biodiversity and its functions in human-disturbed wetlands is an important ecological topic. We surveyed the ecological restoration of a sandpit in the low valley of the Seine River (France) in order to (i) recreate a wet meadow and (ii) study dynamics of restored soils and associated ecological functions. The sandpit was filled with Seine River sediment and covered with alkaline peat by hydraulic way. Several ecological parameters were assessed and more specifically structural parameters (soil physico-chemical properties, plants, collembola and earthworms communities) and functional parameters (plants biomass, C and N mineralization, denitrification process). This communication focuses on the comparison of C and N dynamics in restored peat soils. The restoration of the sandpit leads to the formation of two types of peat soils: (i) hemic Histosol and (ii) interstratified hemic Histosol. This result is related to the variability of sediment and the peat deposition by hydraulic way. These soils show differences in their functioning in relation with C and N dynamics: (i) C mineralization is always lower in the restored meadow than in a reference meadow, (ii) a strong response of denitrification process since to the beginning of inundation gradient controlled by topography, (iii) denitrification in the Hemic Histosol was greater than in the interstratified hemic Histosol. The initial heterogeneity in terms of soil physico-chemical properties and flood frequency level seems determinant on C and N dynamics. Initial soil properties and actual soil functioning can be therefore factors controlling the future dynamics trajectories.

SOIL CARBON AND NUTRIENT CYCLING IN SOUTHEASTERN AUSTRALIAN RIPARIAN ZONES

Cavagnaro Timothy^{*[1]}, Conte Pellegrino^[2], Berns Anne^[3]

^[1]Monash University ~ Australian Centre for Biodiversity ~ Melbourne ~ Australia ^[2]Università degli Studi di Palermo ~ Dipartimento dei Sistemi Agro-Ambientali ~ Palermo ~ Italy ^[3]Agrosphere, Institute of Bio- and Geosciences ~ Agrosphere, Institute of Bio- and Geosciences ~ ~ Germany

Riparian zones represent the last point in the landscape to intercept nutrients and sediments before they enter water bodies. The cycling of nutrients in these sites is, therefore, important. Here we present results of a series of field based experiments. In the first experiment we undertook a detailed survey of soil C sequestration and nutrient cycling at 18 riparian sites that were restored, un-restored or in remnant condition. We found that riparian restoration not only resulted in a build up in soil C, but that the nature of adjacent land use was a major determinant of nutrient dynamics in these sites. In the second experiment we investigated in detail the nature and properties of a soil and nutrient dynamics at the riparian - agriculture interface. Soil physicochemical and vegetation properties were spatially heterogeneous along the gradient sampled. Importantly, both stocks and forms of soil C (measured using ¹³C NMR) varied considerably along this gradient. Furthermore, easily measurable soil and vegetation properties that could be used to predict soil C concentrations at this site were identified using a Bayesian modelling approach. The present paper highlights the dynamic nature of soil processes, the importance of changes in soil properties at interfaces in the landscape, and the need for spatially explicit studies of soil nutrient cycling.

SOIL PROPERTIES AND WATER DISCHARGE NO₃- UNDER INTENSIVE IRRIGATED AGRICULTURE IN A DEGRADED SEMI-ARID MEDITERRANEAN CATCHMENT

Jiménez Juan José^[1], Pedrocchi César^[1], Navarro Enrique^[1], Causapé Jesús^[2], Comín Francisco A.^[1]

^[1]IPE-CSIC ~ Biodiversity Conservation and Ecosystem Restoration ~ Jaca ~ Spain ^[2]Instituto Geológico y Minero de España (IGME) ~ IGME ~ Zaragoza ~ Spain

Semi-arid lands are being transformed to irrigated agriculture to increase crop production and improve rural livelihoods, but also impacting soil (salinization) and aquatic ecosystems (fertilizer and pesticide water runoff to natural water streams). Changes in the diversity of specific soil and aquatic communities can affect delivery of impair ecosystem services. In this study, soil and water related variables were measured along a gradient within a small catchment in the Lerma valley (Zaragoza, NE Spain). Soil pH, texture, soil organic carbon (SOC), soil inorganic carbon (SIC), organic matter fractionation, near infrared spectra (NIRS), elemental analysis, and the presence of terrestrial arthropods were assessed. Ecotoxicological tests were performed with algae to assess irrigation impact of NO₃- excess from adjacent agricultural fields on aquatic ecosystems. SOC concentration was lowest in sediments and highest under natural vegetation. NIRS signals allowed differentiation of mineral soil samples and invertebrate biogenic structures. NO₃- concentration in the lower zone of the catchment has increased during the period 2004-2010 at a yearly rate of 6 mg l⁻¹ and currently has stabilized at 80 mg l⁻¹. Specific conductivity and dissolved NO₃- increased from the uppermost non-irrigated areas (200-400 µS cm⁻¹; 0.1-14 mg L⁻¹) to the intensively irrigated zones (1,800-5,000 µS cm⁻¹; 15-130 mg L⁻¹). Soil arthropod composition differed between sites and dates, and algae growing in the bank-gully showed an increased tolerance to pesticides. These results led to the identification of degradation hotspots related to ecological functions, allowing us to propose corrective measures to reduce nitrate discharge, and biodiversity loss.

S01.02-P -15

USE OF CONSTRUCTED WETLANDS FOR TREATING RUNOFF FROM PEAT EXTRACTION AREAS

Postila Heini^{*[1]}, Karjalainen Satu Maaria^[2], Heikkinen Kaisa^[2], Saukkoriipi Jaakko^[2], Kuoppala Minna^[2], Visuri Mika^[2], Ihme Raimo^[2], Klöve Björn^[1]

^[1]University of Oulu ~ Water Resources and Environmental Engineering Laboratory ~ Oulu ~ Finland ^[2]Finnish Environment Institute ~ ~ Oulu ~ Finland

The aim of the study was to find out how wetlands established to ditched peatland areas, can be used for treating runoff from peat extraction areas. Peat extraction result in harmful loads of phosphorous, nitrogen and suspended matter. The study included six drained wetlands, which were examined for e.g. the hydraulic properties of peat, vegetation, peat thickness, the degree of humification of peat, and the mineral concentrations of peat. The wetlands were also monitored for their capability to remove e.g. nutrients, iron and suspended solids from the runoff. Sampling was carried out by taking water samples from incoming and outgoing water. The results showed that wetlands established to ditched peatland areas, can purify peat extraction runoff. The wetlands retained inorganic nitrogen from the runoff, but some of them leached especially phosphorus, iron and humic substances. When planning wetlands for water purification purposes to ditched peatland areas, attention should especially be paid to the properties of peat (e.g. the concentrations of P, Fe, Al, Mg, Ca, Mn), and the peat thickness in relation to the depth of the ditches.

WATER EXTRACTABLE ORGANIC MATTER IN A RECENTLY RESTORED FLOODPLAIN: THE CASE OF THE THUR RIVER IN NORTHERN SWITZERLAND

Pfeifer Hans-Rudolf^[1], Jane Chaussedent^[1], Géraldine Bullinger-Weber^[4], Claire Guenat^[5], Mohammad Hassouna^[4]

^[1]University of Lausanne ~ IMG-Centre d'Analyse Minérale ~ Lausanne ~ Switzerland ^[2]University of Lausanne ~ IMG-Centre d'Analyse Minérale ~ Lausanne ~ Switzerland ^[3]University of Lausanne ~ IMG-Centre d'Analyse Minérale ~ Lausanne ~ Switzerland ^[4]University of Lausanne ~ Institut de Géologie et de Paléontologie ~ Lausanne ~ Switzerland ^[5]Swiss Federal Institute of Technology ~ Antenne-WSL ~ Lausanne ~ Switzerland

This work was undertaken to determine the effects of bed restoration on the alluvial ecosystem of the river Thur. Water extractable organic matter (WEOM) was used as a potential tracer of the degree of stability of the organic matter of the restored river bed. Nine soil cores of 40 cm length were collected along a 200 m traverse perpendicular to the river, covering the various habitats and including a reference soil corresponding to the situation before restoration. Major and trace metals, total organic and inorganic carbon (TOC/TIC), and total nitrogen TN were analysed. WEOM was obtained from each 10 cm thick soil by a water extraction in the laboratory (water/soil ratio = 1 : 2.5) and then studied with UV/Vis absorption and 3D-fluorescence spectroscopy. Results showed a decrease of WEOM concentrations with depth, especially in undisturbed habitats, such as mixed forest and pasture. A relatively low, almost constant C/N ratio of about 10 was observed. 3D-UV/vis fluorescence results showed a dominance of protein-like fluorophores close to the active river bed, and a humification index HI close to 3 and fulvic-like fluorophores, as well as an increase of humification (HI= 4 to 5) in the habitats farther away. However there is only little variation with depth (HI oscillating +/- 1), indicating that highly reactive organic matter with a rapid turnover dominates and that the system is far from stability. Nevertheless, this type of study allows to delimit the active section of the restored floodplain.

CHANGES IN THE IRON MINERAL ASSEMBLAGE UPON 2000 YEARS OF PADDY CULTIVATION

Vogelsang Vanessa^{*[1]}, Kaiser Klaus^[1], Wagner Friedrich^[2], Fiedler Sabine^[3], Jahn Reinhold^[1]

^[1]Martin-Luther-University of Halle-Wittenberg ~ Soil Sciences ~ Halle ~ Germany ^[2]Technical University of Munich ~ Physics ~ Garching ~ Germany ^[3]Research Center Jülich ~ Institute of Bio- and Geosciences ~ Jülich ~ Germany

More than 9% of the world's arable land is used for rice production (IRRI, 2002), mainly under temporarily submerged conditions (paddy soils). In consequence, distinct redox cycles cause redox-related transformations of Fe hydrous oxides and Fe-bearing clay minerals. We studied changes in the Fe mineral assemblage as evoked by long-term reduction–oxidation cycles along a chronosequence of paddy soils (100, 700 and 2000 year old paddy soils) developed in comparable parent material in the province of Zhejiang, China. Quantitative speciation of Fe mineral phases in top- and subsoil was accomplished by Mössbauer spectroscopy at room temperature and 4.2 K, in combination with x-ray diffraction and selective chemical extractions (DCB, NH₄-oxalate). We found ferrous and ferric iron in silicates, nano- to microcrystalline goethite and haematite, as well as a ferrihydrite-type phase. Prolonged paddy cultivation resulted in an overall loss of Fe hydrous oxides in the topsoil, whereas the Fe mineral assemblage in the subsoil was dominated by increasing contents of microcrystalline goethite. Losses of silicate Fe were slightly higher in the top- than the subsoil. We conclude that long-term submerged rice cultivation leads to re-distribution of Fe mineral phases, obviously resulting from the decoupling of top- and subsoil processes.

Although nitrogen (N) supply drives productivity, poor N fertilizer-use efficiency (FUE-N; 40–60% recovery of applied N) is characteristic of irrigated rice systems. N availability over the cropping season depends on N fertilizer management as well as mineralisation, microbial immobilisation and losses, affected, in turn by agricultural practices such as water and crop residue management. In this work, N uptake by irrigated rice under different crop residue management practices have been compared with the aim of defining best management practices able to enhance FUE-N. The experiment carried out on an ongoing long-term trial in Vercelli (NW Italy), involved comparison between: (i) incorporation of residues in autumn after harvest; (ii) incorporation of residues in spring; (iii) burning of residues after harvest and incorporation in spring; (iii) incorporation of residues in spring and delayed flooding (dry seeding). Fertilizer-N uptake and efficiency during the growing cycle was evaluated by ¹⁵N isotope dilution and difference methods. Early incorporation of crop residues fosters the capability of soil to supply fertilizer- and soil-derived N, essential for increasing N uptake. This was facilitated by the faster and more consistent decomposition of the crop residues during the fallow period, thus limiting fertilizer N immobilisation during the growing season. Burning of crop residues adopted when early incorporation is difficult due to rainfall and/or snow precipitations, will avoid the reduced N availability and consequent reduction in crop growth and N uptake resulting from spring incorporation. Dry seeding did not result in greater N availability for crop uptake, as expected.

In order to assess the sustainability of agrosystems in the famous Hani terraces in Yunnan Province, our research activities focus on the assessment of the soil fertility levels and the discrimination between natural and anthropic determinism of soil nutrient status. As a first step, the soil organization in the landscape, according to geology and relief, was studied after a geomorphopedological approach. The main soil types were identified and classified according to the most recent FAO international classification standards. The soil potentiality and edaphic constraints were assessed by laboratory analysis. Soil fertility diagnosis appears homogeneous in space. Soils are acid, cation exchange capacity and nutrient reserves are low. However, the agrosystem developed by the Hani population has succeeded in maintaining a relatively efficient dynamic of element circulation. Future prospects should focus (i) on the evaluation of the representativeness of the studied area compared to the whole terraced system, (ii) on the measurements of nutrients flows at field scale, (iii) on the effects of soil properties on yields of cultivated crops, and finally (iv) on the up-scaling of field levels results to broader spatial units.

S01.03-P -4

EFFECT OF WATER MANAGEMENT ON DYNAMICS OF RECENTLY FIXED C IN PLANT-SOIL SYSTEM AND MICROBIAL COMMUNITY AT DIFFERENT STAGES OF PLANT GROWTH

Tian Jing^{*[1]}, Kuzyakov Yakov^[1], Pausch Johanna^[2]

^[1]Faculty of Forest Sciences and Forest Ecology ~ Department of Soil Science of Temperate Ecosystems ~ Göttingen ~ Germany ^[2]university of bayreuth ~ AgrarÖkoSystemforschung ~ bayreuth ~ Germany

Water management in rice field is becoming more and more important because more than 2/3 of water will be used for irrigation worldwide. We used $^{14}\text{CO}_2$ and $^{13}\text{CO}_2$ pulse labelling to investigate the effect of water conditions on the distribution of carbon (C) recently assimilated by rice within the plant-soil system and its influence on the soil microbial community under paddy soils. Rice plants were grown under three water treatments: flooded (4-5 cm water level), unflooded (80-85% WHC), and alternating (dry period: 75% WHC; wet period: 4-5 cm water level). The flow of assimilated C from plants to soil C pools was studied at two stages of plant growth: tillering and booting. To distinguish between those stages, plant shoots were pulse labelled with $^{14}\text{CO}_2$ at tillering and with $^{13}\text{CO}_2$ at booting. The ^{14}C activity and ^{13}C content in different C pools were determined 4 times within 14 days after each pulse. Furthermore, microbial community for each treatment was analyzed phospho-lipid-fatty acids (PLFA). The transport of the fixed C from shoots to belowground C pools was very fast for the flooded treatment: ^{14}C decrease in the shoots exponentially within 14 days after the labeling. Comparison of ^{14}C and ^{13}C fluxes showed different partitioning and allocation of recently assimilated C at tillering and booting. Flooding regimes have strong effects on the turnover rates of root-derived C in soil. High proportions of fungal PLFAs were observed for the alternating treatment.

EVOLUTION OF MAGNETIC PROPERTIES AND THEIR PEDOGENETIC IMPLICATIONS FOR THE PADDY SOIL CHRONOSEQUENCES FROM DIFFERENT PARENT MATERIALS IN SOUTH CHINA

Zhang Gan-Lin^{*[1]}, Han Guang-Zhong^[1], Chen Liu-Mei^[1]

^[1]Institute of Soil Science, Chinese Academy of Sciences ~ State Key Lab. of Soil and Sustainable Agriculture ~ Nanjing ~ China

The transformation and translocation of iron oxides are phenomenal during the formation and development of paddy soils (Hydragric Anthrosols). Our study of the paddy soil chronosequences from quaternary red clay (QRC), red stone residues (RSR) and purple shale residues (PSR), with different cultivation ages in South China indicates that the magnetic susceptibility (MS), saturation isothermal remanent magnetization (SIRM) and soft isothermal remanent magnetization (IRMs) of all non-paddy soils (original soils) vary significantly with parent materials and obviously decrease with depth. The synchronous decrease of MS, SIRM and IRMs remarkably occur in anthrostatic epipedon at the initial cultivation stage and they will be soon reduced to extreme low values and tend to maintain at a stable level with increasing paddy cultivation age. In contrast, there are no notable decreases of these magnetic parameters and even they increase obviously in hydragric horizons of the young paddy soil profiles derived from PSR and RSR. Nevertheless, these magnetic parameters in hydragric horizons of the paddy soils derived from QRC decline gradually with the increasing of cultivation age with smaller range than those in anthrostatic epipedons. The variation characteristics of MS, SIRM and IRMs is related to the differentiation of the redox condition between anthrostatic epipedon and hydragric horizon which favors the ferrimagnetism minerals formation and represents one kind of mechanism of magnetic enhancement in the soils. Our observation also indicates that magnetic enrichment generally occurs in the clay fractions and the ferrimagnetic minerals of clay are more easily damaged in paddy soils.

INCREASED CO₂ FLUXES UNDER WARMING TESTS AND SOIL SOLUTION CHEMISTRY IN A HISTIC CRYOSOL FROM SALLUIT, NUNAVIK (QC, CANADA)

Fouché Julien^{*[1]}, Keller Catherine^[1], Ambrosi Jean Paul^[1], Allard Michel^[2], Brault Manon^[1]

^[1]Aix Marseille Université, CNRS, CEREGE ~ Département Sol, Eau, Déchets ~ Aix en Provence ~ France ^[2]CEN, Université Laval ~ Département de géographie ~ Quebec ~ Canada

Permafrost-affected soils under tundra ecosystems contain large stocks of organic carbon. Global warming could induce an Arctic ecosystems positive feedback on global C release. Instrumentation was installed in Salluit (Nunavik; 62°14'N, 75°38'W) to monitor respiration of a Histic Cryosol in a polygonal peatland under current and warmer conditions and its relationship with variations in soil solution composition. C and N mean contents in topsoil were respectively 280 and 14 g/kg DW. An open top chamber was installed to modify thermal conditions in the active layer. All samples, measurements and analyses were performed in both normal (N) and transformed (T) conditions from mid July to end of August 2010. The profile temperature was monitored hourly and soil respiration (SR) was measured daily every second day with a respiration chamber linked to a portable IRGA. Soil solutions were sampled every two days using tension-free lysimeters installed at 10 and 30 cm depths and analysed for dissolved organic carbon (DOC), total dissolved nitrogen (TDN) and major elements. In natural conditions, average SR was 0.96 $\mu\text{molCO}_2\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. An increase of the surface temperature of 2.5°C was observed and led to an 80% enhancement of SR at the T station (1,73 $\mu\text{molCO}_2\cdot\text{m}^{-2}\cdot\text{s}^{-1}$). The soil solution is weakly mineralized and there were no differences in composition between the two stations. Mean DOC and TDN contents were 36 and 1.5 mg.L⁻¹ respectively. The induced warming increased CO₂ fluxes. This impact appears to be striking in Histic Cryosols despite low SR values in natural conditions.

LIMITATION OF MECHANICAL ANALYSIS OF SHRINKAGE AND SWELLING OF PADDY SOIL - FROM THREE YEARS MONITORING OF WRC IN A PADDY FIELD-

Yoshida Shuichiro*^[1]

^[1]The University of Tokyo ~ Biological and Environment Engineering ~ Tokyo ~ Japan

Paddy soil, which is puddled and submerged, shows remarkable shrinkage when it dries. However the soil cannot swell up to the original volume when it is submerged again. This cyclic change in paddy soil structure is partly modeled by elasto-plastic mechanics coupled with the pore water movement. However the shrinkage and swelling under the drastic change in redox condition is more complicated than the simple mechanical deformation. Present study observed cyclic shrinkage and swelling of clayey paddy soil with regard to the water management during the cultivation of rice and precipitation in fallow periods. The change in soil structure is monitored by a Water Retention Characteristics (WRC). Undisturbed soil samples were taken repeatedly at same locations and depths of a clayey experimental paddy at submerged condition (mid-summer), dried condition (mid-summer) and before tillage (early spring). The samples were saturated first, then drained to -80kPa (1st desorption), saturated again, and finally drained to -80kPa again (2nd desorption) in a pressure chamber. Compression index, representing plastic shrinkage, and swelling index, representing elastic swelling, were evaluated from the 1st and 2nd desorption curves. The results shows the pores subject to the plastic deformation largely decreased after the desiccation of the field, but they were partly recovered by wet condition such as much precipitation and snow accumulation in winter. Because the observed recovery of plastic pores cannot be explained by elasto-plastic mechanics, it suggests existence of change in the WRC due to time-dependent redox condition induced by the variation in water regime.

MAGNESIUM SULPHATE VERTIC PADDY SOILS IN THE NIGER RIVER VALLEY (KOLLO, NIGER)

Adam Issifou*^[1], Michot Didier^[1], Caner Laurent^[2], Montoroi Jean-Pierre^[3], Guéro Yadjji^[4], Guéro Yadjji^[7], Walter Christian^[1]

^[1]UMR 1069 Sol-AgroHydrosystèmes-Spatialisation ~ Agrocampus-Ouest / INRA ~ Rennes ~ France ^[2]UMR 6269 HYDRASA ~ Université de Poitiers ~ Poitiers ~ France ^[3]UMR 211 Bioemco ~ IRD ~ Bondy ~ France ^[4]Laboratoire science de sol-Faculté d'Agronomie ~ Université de Niamey ~ Niamey ~ Niger ^[5]Laboratoire science de sol ~ Université de Niamey ~ Niamey ~ Niger ^[6]Laboratoire science de sol-Faculté d'Agronomie ~ Université de Niamey ~ Niamey ~ Niger ^[7]Faculté d'Agronomie ~ Université de Niamey ~ Niamey ~ Niger

Paddy Vertisols located in the irrigated scheme of Kollo (Niger) have distinct characteristics from other irrigated paddy soils observed along the Niger River valley. They present some properties diagnostic to acid sulphate soils, never described before in a continental alluvial valley. This study aims to characterize in detail these Vertisols in order to infer the underlying pedogenetic processes. Each soil horizon from 4 profiles was analysed to identify: i) physicochemical properties; ii) mineralogy of clays, oxides and salt efflorescence, iii) hydrodynamic and structural properties and cracks distribution in dry conditions. The soil profiles studied were characterized by clay content higher than 80%, pH in water between 3 to 5 and high salinity with an electrical conductivity of saturated paste ranging from 13 to 29 dS.m⁻¹ from the surface to 1.2 m depth. Mg and Na were dominant cations and S the main anion. Moreover Ca et Mg were the dominant exchangeable cations with a ratio Ca/Ma lower than 0.6. DRX showed the occurrence of kaolinite, smectite, illite and goethite. Salinity appeared controlled by the precipitation or the dissolution of magnesium and calcium sulphates: hexahydrate, epsomite and gypsum. In water saturation conditions, the hydraulic conductivity of horizons was lower than 2.10⁻⁸ m.s⁻¹. The coefficient of linear extensibility derived from shrinkage curve ranged from 0.22 to 0.24 showing that these soils are very deformable. Paddy soils studied at Kollo were identified as vertic Solontchak or salic Vertisol.

MECHANISMS OF PADDY SOIL CRACKS GENERATION AND ITS CONSEQUENCES ON PREFERENTIAL FLOW

Peng Xinhua^{*[1]}, Zhang Zhongbin^[2], Zhou Hu^[3]

^[1]Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China ^[2]Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China ^[3]Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China

In this paper we selected two paddy soils (one has been cultivated for 20 years and the other one for >100 years) to investigate Fe/Al leaching and soil organic matter accumulation on cracks generations. Wetting and drying intensity and frequency on soil shrinkage will be also presented. Pore rigidity will be proofed by aggregate pores changes using synchrotron radiation x-ray micro-CT method. We wish to find the agreement between pore change at microscale and bulk soil shrinkage at soil core scale. We also wish fill the gap between shrinkage of soil core determined in the laboratory and cracks in the field. Finally the consequences of cracks on water infiltration will be discussed.

MODELING THE FATE OF PESTICIDES IN PADDY RICE – FISH POND FARMING SYSTEMS IN NORTHERN VIETNAM

Lamers Marc*^[1], La Nguyen^[1], Streck Thilo^[1]

^[1]University of Hohenheim ~ Institute of Soil Science and Land Evaluation ~ Stuttgart ~ Germany

During the last decades, high population growth and export-oriented economics in Vietnam have led to a tremendous intensification of rice production, which in turn has significantly increased the amount of pesticides applied in cropping systems. In Vietnam, there is concern that paddy rice production systems are the major non-point sources for pesticide pollution of surface- and groundwater. The quantification of pesticide losses from paddy rice fields to rivers and the assessment of associated risks are hampered by the limited availability of field data. One potential way out is the use of simulation models. Therefore, we developed a new, process-based model to simulate short-term pesticide dynamics in integrated paddy field - fish pond farming systems under the specific environmental conditions of south-east Asia. State of the art approaches and algorithms to describe the fundamental physical-chemical processes were combined and numerically solved using the ordinary differential equation (ODE) solver Berkeley Madonna (Version 8.0.1). The model was automatically calibrated for two pesticides (fenitrothion, dimethoate) by means of the Levenberg-Marquardt algorithm and validated against data measured in 2008 in a typical paddy rice – fishpond system in northern Vietnam. In our presentation we will introduce the basic structure of our model and present simulation results indicating that the model is a useful tool for simulating the fate of pesticides in paddy rice farming systems.

NITROGEN AVAILABILITY IN FERTILIZED PADDY SOILS AS A FUNCTION OF REDOX CONDITIONS AND RICE STRAW INCORPORATION

Cucu Maria Alexandra^{*[3]}, Said-Pullicino Daniel^[3], Maurino Valter^[2], Celi Luisella^[3]

^[1]University of Turin ~ DiVaPRA - Agricultural Chemistry and Pedology ~ Turin ~ Italy ^[2]University of Turin ~ Department of Analytical Chemistry ~ Turin ~ Italy ^[3]University of Turin ~ Soil Biogeochemistry Team, Rice Agro-ecosystem and Environmental Research Group ~ Grugliasco ~ Italy

Nitrogen (N) availability in fertilized rice paddies is the result of a balance of processes mainly the gross rates of N mineralization, microbial immobilization and N losses. Water and crop residue management practices often confound these established relationships making N the most difficult nutrient to manage in rice cropping systems. Detailed information on the driving processes and factors controlling N availability in paddies is therefore highly necessitated. This study aims at investigating and quantifying the interactive effects of soil redox conditions and straw incorporation on fertilizer-N availability in paddy soils. A paddy soil was treated with enriched ammonium-15N and incubated for 160 days under flooded or non-flooded conditions, with or without the addition of rice straw. Changes in total and fertilizer-derived inorganic N forms as well as immobilized N and dissolved organic C with incubation time were determined. The addition of straw significantly reduced N availability under oxic conditions, probably due to the microbial immobilization of the added N in the presence of straw (C/N = 60). In contrast, in anoxic soils straw incorporation resulted in a significant increase in net N supply. Nonetheless, the immobilization of about 47 and 32% of applied N was observed in straw-amended and non-amended anoxic soils, respectively. These results suggest that under anoxic conditions, soil or straw-derived organic matter mineralization could contribute to N availability, partially compensating for the immobilized fertilizer-N. Higher DOC concentrations in straw-amended anoxic soils further point to the supply of labile organic matter for microbial mineralization.

ORGANIC CARBON ACCUMULATION IN A 2000-YEAR CHRONOSEQUENCE OF PADDY SOIL EVOLUTION

Wissing Livia^{*[3]}, Kölbl Angelika^[4], Cao Zhi-Hong^[5], Kögel-Knabner Ingrid^[6]

^[1]Lehrstuhl für Bodenkunde, Technische Universität München ~ Ecology and Ecosystem Management, , Center of Life and Food Sciences Weihenstephan ~ Freising ~ Germany ^[2]Lehrstuhl für Bodenkunde, Technische Universität München ~ Ecology and Ecosystem Management, , Center of Life and Food Sciences Weihenstephan ~ Freising ~ Germany ^[3]Lehrstuhl für Bodenkunde, Technische Universität München ~ Ecology and Ecosystem Management, , Center of Life and Food Sciences Weihenstephan ~ Freising ~ Germany ^[4]Lehrstuhl für Bodenkunde, Technische Universität München ~ Ecology and Ecosystem Management, , Center of Life and Food Sciences Weihenstephan ~ Freising ~ Germany ^[5]Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China ^[6]Lehrstuhl für Bodenkunde, Technische Universität München ~ Ecology and Ecosystem Management, , Center of Life and Food Sciences Weihenstephan ~ Freising ~ Germany

Large proportions of the terrestrial carbon are accumulated in wetland rice soils. The stabilization of organic carbon (OC) is often accompanied by the presence of iron (Fe) oxides and fine mineral particles. The study aimed to allocate the OC distribution within the soil fractions and to assess the OC stabilization by interactions with surfaces of Fe oxide and other fine mineral particles during pedogenesis. A paddy chronosequence of six age groups was chosen in the Zhejiang Province, ranging from 50 to 2000 years of rice cultivation. A physical fractionation was applied to the topsoils in order to isolate medium, fine silt and coarse, fine clay fractions. Fractions were analyzed for their OC concentrations and dithionite (Fed) and oxalate (Feo) extractable Fe oxides. The specific surface area (SSA) was determined by using BET-N₂ (before and after removal of organic matter) to estimate the OC coverage of the different surfaces. Results showed a low SSA and high accretions of OC with pedogenesis in medium silt fraction. Clay fractions were characterized by the highest Feo content, a high SSA and low OC accretions during pedogenesis. The results lead to the assumption that OC stabilization in clay and medium silt fractions seems to be caused by different processes. We assume that formation of stable microaggregates is a relevant process for OC stabilization in silt fractions, whereas the formation of organo-mineral associations by a reactive mineral surface of Feo oxides seems to be the major mechanism for OC stabilization in clay fractions.

PHYSICO-CHEMICAL PROPERTIES OF PEAT SOIL AT DIFFERENT DEGREE OF ORGANIC MATTER DECOMPOSITION IN DEEP SOIL PROFILES

Szafranek-Nakonieczna Anna^{*[1]}, Stepniewska Zofia^[1], Banach Artur^[1]

^[1]The John Paul II Catholic University of Lublin ~ Department of Biochemistry and Environmental Chemistry ~ Lublin ~ Poland

Peatlands are one of the most common landscape elements of the Lublin Polesie Region, which cover about 25% of its area. A small percentage of this peatland are transitional bog, usually occur near eutrophic lakes. One of them is transitional bog, 30–150 m wide belt surrounding Moszne Lake. The vegetation is composed of peatmosses and sedges and peat accumulation in this region is reported in the range from 1 to 0.3 mm/year. Mineral substratum of organogenic deposits is composed of the Late Vistulian sandy silts and limnic sands. Thickness of peat varied between 3.5 and 7.0m. Slow rate of peat accumulation causes that the deepest layer of that profile might be formatted about 3500 and even 23000 years ago from different species of plant. The aim of present work was to examined how physico-chemical properties of peat changes in peat profile, from the surface, poorly decomposed plant remains, across well decomposed peat and gytja layers up to mineral substrate. For that reason two outcrop by Eijkelpkamp drill were made and soil samples were taken. In laboratory peat material was exterminated in terms of: pH, Eh, EC, moisture, and content of bioavailable forms of nitrogen and phosphorus. This analysis allowed us to found gradients of physico-chemical parameters in peat profile in relation to carbon accumulation and water level.

**PROCESS AND AMOUNT OF GASEOUS EMISSION FROM A TROPICAL PEATLAND FIRE
OBSERVED IN A FIELD EXPERIMENT IN CENTRAL KALIMANTAN, INDONESIA**

Hamada Yohei^[1], Darung Untung^[2], Limin Suwido H.^[2], Hatano Ryusuke^[3]

^[1]Hokkaido University ~ Faculty of Environmental Earth Science ~ Sapporo ~ Japan ^[2]University of Palangka Raya ~ CIMTROP ~ Palangka Raya ~ Indonesia ^[3]Hokkaido University ~ Research Faculty of Agriculture ~ Sapporo ~ Japan

Fire is the most radical form of carbon emission, especially in peatlands where soil itself is burnt away. Few studies have conducted a field scale fire experiment in tropical peatland. In this study a small scale field experiment of peat burning was conducted to evaluate the process and amount of gaseous emission by fire. A 3-m by 4-m plot was prepared in Central Kalimantan, Indonesia. The topsoil was plowed and exposed for a week. Concentrations of CO₂, CO, CH₄, N₂O, and PM were observed at heights of 1.0, 0.5, 0.0, -0.1 and -0.2 m. Soil temperature at -0.1 and -0.2 m was recorded every 10 minutes. Twelve iron pipes were installed to measure the depth of peat loss. After ignition, flaming stage of peat burning was ceased within 2-3 hours. The following smoldering stage continued for a week. The averaged burnt depth was 7.5 cm. Based on bulk density of 0.22 g/cm³ and carbon content of 55.5%, the amount of carbon lost from the plot was 110.2 kg. In the flaming stage, soil temperature at -0.1 m increased tentatively. After the smoldering stage began, the temperature rapidly increased to 350–450°C. Response of soil temperature at -0.2 m was less prominent; it reached 50–100°C at the maximum. Concentrations of gaseous components became maximal in the flaming stage. During the smoldering stage, the concentrations gradually decreased. The influence of burning on CO₂ and PM was prominently remained at -0.1 m, whereas those at -0.2 m were not so much.

SHIFTS OF NITROGEN TRANSFORMING MICROBIAL COMMUNITIES DURING PADDY SOIL EVOLUTION

Schlöter Michael*^[1], Bannert Andrea^[4], Kleinedam Kristina^[3]

^[1]Institute of Soil Ecology ~ Terrestrial Ecogenetics ~ Neuherberg ~ Germany ^[2]Institute of Soil Ecology ~ Terrestrial Ecogenetics ~ Neuherberg ~ Germany ^[3]Institute of Soil Ecology ~ Terrestrial Ecogenetics ~ Neuherberg ~ Germany

^[4]Institute of Soil Ecology ~ Terrestrial Ecogenetics ~ Neuherberg ~ Germany

In many areas of China, tidal wetlands have been converted into agricultural land for rice cultivation. However, the consequences of land-use changes for soil microbial communities are poorly understood. Therefore, we investigated bacterial and archaeal communities involved in inorganic nitrogen turnover (nitrogen fixation, nitrification, and denitrification) based on abundances and diversity pattern of the corresponding functional genes along a soil chronosequence ranging between 50 and 2,000 years of paddy soil management compared to findings for a tidal wetland. Changes in abundance and diversity of the functional groups could be observed, reflecting the different chemical and physical properties of the soils, which changed in terms of soil development. The tidal wetland was characterized by a low microbial biomass and relatively high abundances of ammonia-oxidizing microbes. Conversion of the tidal wetlands into paddy soils was followed by a significant increase in microbial biomass. While relative abundances of nitrogen fixation genes as well as diversity pattern changed soon after tidal wetland conversion, gene abundance pattern of denitrification showed only after 300 years of paddy soil development significant shifts. With ongoing rice cultivation, copy numbers of archaeal ammonia oxidizers did not change, while that of their bacterial counterparts declined. In general, changes in diversity patterns were more pronounced than those in functional gene abundances.

S01.03-P -16

SPATIAL DISTRIBUTION OF SOIL ORGANIC CARBON DURING PADDY SOIL EVOLUTION

Kölbl Angelika^[1], Cornelia Müller-Niggemann^[2], Lorenz Schwark^[2], Zhihong Cao^[3], Ingrid Kögel-Knabner^[1]

^[1]Lehrstuhl für Bodenkunde (Soil Science) ~ Ecology and Ecosystem Management ~ Freising ~ Germany ^[2]Institute of Geoscience ~ Christian-Albrechts-University ~ Kiel ~ Germany ^[3]The Institute of Soil Science ~ Chinese Academy of Sciences ~ Nanjing ~ China

In the Zhejiang province (Yangtze River Delta, PR China), consecutive land reclamation by construction of protective dikes during the past 2000 years led to a unique chronosequence of soil formation. Parts of the land are used for paddy rice production. These soils document the effect of paddy soil management on the amount and spatial distribution of soil organic carbon (SOC) during pedogenesis. We hypothesised that the spatial pattern of SOC change with increasing duration of paddy soil use, leading to spatial homogenisation of topsoils due to frequent puddling, but increased spatial heterogeneity of undisturbed subsoils due to ongoing transport and relocation processes. Three plots of the chronosequence (50, 300 and 1000 years of paddy cultivation) were sampled on the basis of regular, orthogonal grids. Samples were taken from puddled topsoils, plough layers, and mixed subsoil layers. Beside SOC concentrations, soil lightness was measured to check if colour measurements allow predicting the amount and distribution of SOC. The results showed no spatial dependence of SOC at the youngest paddy plot, underlining the homogeneity of the parent material. With increasing duration of paddy soil use, an increasing degree of spatial dependence was observed. Different spatial patterns in all soil depths indicate that the compacted plough layer decoupled the SOC distribution between topsoil and subsoil. Soil lightness measurement was not sufficient to predict the amount and distribution of SOC. To conclude, paddy soil evolution is strongly associated with the development of spatial dependencies of SOC even in intensively managed topsoil layers.

S01.03-P -17

STABILIZATION OF ORGANIC MATTER UNDER DIFFERENT REDOX CONDITIONS

Hanke Alexander^[1], Vogelsang Vanessa^[2], Cerli Chiara^[1], Fiedler Sabine^[3], Kaiser Klaus^[2], Kalbitz Karsten^[1]

^[1]Universiteit van Amsterdam ~ Institute for biodiversity and ecosystem dynamics ~ Amsterdam ~ Netherlands ^[2]Martin-Luther-Universität Halle ~ Institut für Agrar- und Ernährungswissenschaften ~ Halle ~ Germany ^[3]Forschungszentrum Jülich ~ Institut für Bio- und Geowissenschaften ~ Jülich ~ Germany

Stabilization of organic matter (OM) is crucial to soil functions and carbon cycling. Stabilization by interactions with soil minerals has been studied mainly under oxic conditions while effects of different redox conditions have not been investigated so far. We coated three minerals (ferrihydrite, goethite, nontronite) with OM derived from decomposed rice straw. The OM-coated minerals were incubated either suspended in water or in an extract of fresh rice straw for one year, exposed to solely anoxic, solely oxic and alternating redox conditions. Stabilization of adsorbed OM under oxic and alternating conditions was similar and more efficient under anoxic conditions. Carbon mineralization was largest for ferrihydrite and nontronite (39-43% and 40-56% of initial total organic C) and smallest for goethite (20-38%), indicating best stabilization by goethite. The availability of easily degradable DOM had only a small negative effect on OM stabilization (0-8% additional mineralized C of initial TOC). Considering the smaller specific surface area (SSA) of goethite (48 m² g⁻¹) than of ferrihydrite (290 m² g⁻¹), the better stabilization by goethite might result from fractionation of OM during adsorption, where highly competitive and stable compounds such as phenolic acids adsorbed preferentially. We conclude that stabilization of OM by interactions with minerals was less dependent on redox conditions than expected. Fractionation of OM during adsorption strongly affected stabilization. Type of the mineral and SSA are no straight forward indicators for OM stabilization.

SUBSOIL CARBON DYNAMICS UNDER PADDY MANAGEMENT

Bräuer Tino^{*[2]}, Grootes Pieter M.^[2], Nadeau Marie-Josée^[2], Andersen Nils^[2]

^[1]Leibniz-Laboratory ~ Christian-Albrechts-University of Kiel ~ Kiel ~ Germany ^[2]Leibniz-Laboratory ~ Christian-Albrechts-University ~ Kiel ~ Germany

Paddy and non-paddy soils from a chronosequence of 50 to 2000 years of agricultural use, developed on former estuarine sediments of the Yangtze River, were sampled near Cixi, Zhejiang Province, China. In addition samples of Yangtze River estuarine sediments were obtained. ^{14}C documents a replacement of "old" carbon by "modern" carbon in both paddy and non-paddy topsoils within 50 to 100 years. Different ^{14}C and organic carbon (OC) depth gradients develop in the subsoil of paddy and non-paddy sites due to the reduced transport of OC through the plough pan into the paddy subsoil. Our results reveal two pathways for OC transport into the (deep) subsoil. The first is fresh plant material. Rootlets and plant material with modern ^{14}C concentrations (range 101 % to 128 % of the modern standard) were found far below the plough pan. Fresh root material and root exudates provide a subsoil input of organic carbon derived from the recent atmosphere. The second pathway of "young" carbon into the subsoil is transport as DOM. Fractionation of the humus into insoluble humin, alkali soluble humic acids, and acid soluble fulvic acids reveals a fulvic acid OC content around 50 % of the bulk TOC and 10 to 20 % humic acids with ^{14}C concentrations up to 40 percent modern higher than the ^{14}C concentration of the bulk soil. Therefore this soluble fraction is of importance for the relocation of young OC into paddy subsoils.

S01.03-P -19

THE CONTRIBUTION OF MINERALIZATION TO GRASSLAND N UPTAKE ON PEATLAND SOILS WITH ANTHROPOGENIC A HORIZONS

Sonneveld Marthijn*^[1], Lantinga Egbert^[2]

^[1]Wageningen University ~ Land Dynamics Group ~ Wageningen ~ Netherlands ^[2]Wageningen University ~ Biological Farming Systems Group ~ Wageningen ~ Netherlands

Peatland soils contain large amounts of nitrogen (N) in the soil and mineralization can contribute substantially to the annual mineral N supply of grasslands. We investigated the contribution of N mineralization from peat with respect to the total annual N uptake on grasslands with anthropogenic A horizons and submerged tile drains. The study included i) a pot experiment to determine potential N mineralization from the topsoil and the subsoil, ii) a 1-year field experiment to study herbage yields and N uptake under fertilized and non-fertilized conditions and iii) a 3-year field study where herbage yield and N uptake from the top 30 cm and the entire soil profile were monitored. The 3-year field study yielded an average N uptake of 342 kg ha⁻¹ under non-fertilized conditions but the contribution of subsoil peat N mineralization to the total N uptake was found to be negligible. Our calculations demonstrate that peat N mineralization contributed only 10% to 30% to the total N-uptake, mainly coming from the top 30 cm. Most of the N uptake under unfertilized conditions appears to be largely the result of mineralization from long-term inputs of dung, ditch sludge, farmyard manure, cow slurry and non-harvested herbage.

THE FATE OF PESTICIDES IN A RICE PADDY WATERSHED IN NORTHERN VIETNAM

Gut Thomas^{*[1]}, Lamers Marc^[1], Nguyen Van Vien^[2], Streck Thilo^[1]

^[1]University of Hohenheim ~ Institute of Soil Science and Land Evaluation - Biogeophysics Section ~ Stuttgart ~ Germany ^[2]Hanoi University of Agriculture ~ Plant Protection ~ Hanoi ~ Viet nam

During the past decades, paddy rice production in Vietnam has undergone a major intensification due to population growth and increasing export-market orientation. As a consequence, the amount of applied pesticides has been tripled during the last decade.. Recent studies from the major rice cultivating regions in Europe and Japan indicate, that a considerable fraction of applied pesticides are lost from the target area to surface water compartments, such as lakes or rivers. For south-east Asia in general and Vietnam in particular studies on the fate of pesticides in paddy rice cultivating regions are limited. The aim of the present study is to assess and evaluate the fate of widely applied pesticides in paddy rice watersheds in northern Vietnam. In 2009, we installed gauging stations at an upstream, midstream and downstream position of a watershed. At each station we measured discharge and we automatically sampled water for pesticide analyses. . Furthermore, we conducted field surveys among 140 rice farmers to gain knowledge on the application practices. Key results indicate that according to their physico-chemical properties a significant fraction of the applied mass of pesticides is lost from the paddy fields to the receiving stream. In our presentation we will focus on the experimental setup and key results indicating that, under the current management practice, pesticide use in paddy fields poses a serious environmental problem in northern Vietnam.

VERTIC PROPERTIES AND RELICS OF GILGAI MICRORELIEF IN STAGNIC CHERNOZEMS ON THE SILESIAN LOWLAND, SW POLAND

Kabala Cezary^{*[1]}, Plonka Tomasz^[2], Przekora Agnieszka^[1]

^[1]Wrocław University of Environmental and Life Sciences ~ Institute of Soil Science ~ Wrocław ~ Poland ^[2]University of Wrocław ~ Institute of Archaeology ~ Wrocław ~ Poland

Soils with a specific lithological discontinuity are widespread in eastern part of the Silesian Lowland, where the Neogene swelling clays (smectite-illite) are covered with eolian silts or silt loams of the Pleistocene age. Unusual Stagnic Chernozems (or Mollic Planosols), found within a shallow land depression close to the archaeological site near Tyniec, have deep humus horizon with wavy-shaped lower boundary extending from 50 to 100-110 cm below soil surface. In a cross section, these forms resemble "cavities" filled with homogenous material, silt-loamy and rich in humus, surrounded by "embankments" of clay material extending from the subsoil. Within the clay material, wedge-shaped aggregates are abundant, all having glossy surfaces (slickensides), both on top and bottom sides. Longer axes of wedge-shaped aggregates are aligned under smallest angle below the "cavities" and the largest (up to 60o) within "embankments" separating the caves. In the course of studies, successively was rejected possibility of an anthropogenic or cryogenic origin of the subsurface forms. More than 300 "cavities", revealed after removing of upper 50 cm of humus horizon, form the basis for former gilgai microrelief, today invisible due to ground leveling and ploughing. Present-day activity of sub-surface clay swelling and shrinkage is unknown, but probably low due to dense drainage pipe system installed at the depth of 60-70 cm below soil surface. This is probably the first finding of such a well preserved relic of a gilgai microrelief and wedge-shaped structure in Poland, where the vertic properties in soils are reported in general not often.

WORLD ATLAS OF ORGANOC SOILS IN PEATLAMDS

Montanarella Luca^{*[1]}, Jones Arwyn^[1], Tarnocai Charles^[2], Broll Gabriele^[3]

^[1]European Commission ~ Joint Research Centre ~ Ispra ~ Italy ^[2]Agriculture and AgriFood Canada ~ Research Branch ~ Ottawa ~ Canada ^[3]University of Osnabruck ~ Institute for Geography ~ Osnabrueck ~ Germany

The European Commission's Joint Research Centre is planning to launch a new title in its popular Soil Atlas series. Focusing specifically on organic soils of peatlands, this new publication aims to present an overview of the nature and importance of these soils. Targeted at the non-specialist reader, the atlas will introduce the concept of organic soils, their formation, properties, functions and services performed and potential threats. The atlas will present a global perspective showing the occurrence various ecozones (polar, boreal, temperate and tropical). The presentation will outline the initial structure and contents and identify data needs, areas of collaboration sought and timetable and roadmap for completion. On completion, such an atlas will be a valuable tool for policy maker, the education sector and the public to help them understand the value of this particular soil type.

ZINC DYNAMICS ASSOCIATED WITH REDOX-ACTIVE SPECIES IN SELECTED PADDY SOILS

Bunquin Michelle Anne^[1], Beebout Sarah^[1], Castillo Oliver^[1], Tandy Susan^{*[2]}, Schulin Rainer^[2]

^[1]International Rice Research Institute ~ Crop and Environmental Sciences Division - Soils ~ Los Baños Laguna ~ Philippines ^[2]ETH Zürich ~ Soil Protection - Institute for Terrestrial Ecosystems ~ Zürich ~ Switzerland

Zinc dynamics in paddy soils plays an important role in rice productivity and, more extensively, in human nutrition, as zinc-deficient rice affects the zinc intake of humans who depend on rice as their staple food. We studied the reductive dissolution of iron and manganese and the formation of sulfide under varying redox conditions, using a stirred soil slurry microcosm system that could be made anaerobic by continuous flushing with nitrogen. As the soil redox potential decreased from +200 mV to –300 mV, the following parameters were measured: water-soluble zinc, iron and manganese; sulfate in soil solution; and sulfide in slurry and in soil solution. Geochemical modeling of soil solution data from two contrasting soils using Visual Minteq indicated that sulfide reactions controlled Fe²⁺, Mn²⁺, and Zn²⁺ solubility, even at relatively high redox potential in a high-sulfate soil, while sorption of metals onto iron and manganese oxides, in addition to sulfide formation, was the predominating redox-active process affecting zinc availability at relatively low redox potentials in the soils. This study provides new insights on how zinc availability could vary in different soil types and how adsorption and precipitation mechanisms could affect the release of zinc in the soil.

Bricks are regularly reported to contribute to an important amount of the coarse fraction in urban soils. Bricks are produced, used and finally dumped into soils for more than 2000 years now. Surprisingly little is known about their functions in urban soils. Blume & Runge (1978) quantified brick contents in coarse fractions of Rendzinas from rubble in Berlin and found up to 56% (m/m) of the subsoil material are bricks. Trinks et al. (2007) showed that bricks from coarse fractions have high porosities of up to 45% (v/v) which might enhance the water availability of a soil depending on the fine earth texture. Blume & Runge (1979) as well as Trinks et al. (2007) hypothesized that due to the discontinuous pore system the exchange of water between coarse bricks and fine earth may be hindered. There is no information available on the brick contents in the fine earth fraction, nor on their chemical features like cation exchange capacity (CEC) or exchangeable cations. It was hypothesized, that because of the porosity of the bricks their CEC is not depending on their particle size. Rooting of bricks, similar to rooting of Granites (Jongmans et al., 1997) has not been observed so far but can be expected. It's the goal to (i) discuss bricks and brick particles as markers for an urbanisation impact on soils and (ii) to study the chemical characteristics of bricks in soils and to (iii) analyse, whether resources supplied by bricks are accessible for plants.

CONTAMINATION AND TRANSFORMATION OF TOPSOIL HORIZONS IN URBAN PARKS ON THE BASIS OF MAGNETIC SUSCEPTIBILITY MEASUREMENTS

Lukasik Adam^{*[1]}, Strzyszcz Zygmunt^[1], Szuszkiewicz Marcin^[1]

^[1]Institute of Environmental Engineering Polish Academy of Sciences ~ Land Reclamation ~ Zabrze ~ Poland

Urban parks are integral and stable elements of town architecture, that underwent continuous changes accompanying agglomeration development. Soils of those areas through their contamination and transformation of uppermost horizons reflect direct and indirect influence of human activity on environment. Vegetation of urban parks (mainly trees) significantly modifies distribution of air pollutions into soil surface. Urban-industrial dusts of various origins (steelworks, power plants, coking plants, traffic pollutions, low emission) besides heavy metals contain ferromagnetics. Their presence in soils can be detected by magnetic susceptibility (MS) measurements. Topsoil horizons featuring elevated contents of ferromagnetics (magnetic anomaly) as well as heavy metals (geochemical anomaly) indicate to strong anthropopression on the environment. The study were conducted in four urban parks in Upper Silesia (Poland) large conurbation. Field measurements have been conducted in dense grid on open space areas (lawns, meadows) and under tree canopies. Magnetic susceptibility measurements both volume (?) and specific (?), covered in situ campaign (surface measurements of ?) and ex situ (soil core measurements of ? and soil sample analysis for ?). Heavy metal contents in soil samples from A horizons have been determined by ASA method after extraction in aqua regia. Obtained data indicate on presence of ferromagnetics and heavy metals in topsoil horizons as results of dust deposition and presence of artifacts. Spatial diversity of magnetic and geochemical anomalies is a result of direct human activity (dust imissions, presence of artifacts in soil) and specific features of individual urban park (tree species content, architecture, and distance to emitters).

HEAVY METALS CONTENT IN EDIFISOLS - SOILS FORMING ON THE BUILDINGS

Przemyslaw Charzynski^[1], Marcin Chmurzynski^[2], Michal Dabrowski^[2]

^[1]Nicolaus Copernicus University ~ Department of Landscape Geography ~ Torun ~ Poland ^[2]Nicolaus Copernicus University ~ Department of Soil Science ~ Torun ~ Poland

Soil sampling was carried out in the three countries: Poland, Romania and Spain. Samples were taken from 21 sites separated into three types: top of the building (roof), wall of the building and gutter. Aim of the studies was to determine the concentrations of selected heavy metals in edifisols. In the soil samples the content of lead, copper, zinc and cadmium was determined using Atomic Absorption Spectrophotometry. The concentration of lead in the analyzed soils ranges from less than 16 mg · kg⁻¹ to 365 mg · kg⁻¹. The differentiating factor may be distance of the study sites to the traffic routes, where, despite the downward trend in recent years, the concentration of this element in the air is still elevated, what is confirmed by monitoring carried in Torun. The concentration of copper ranges from less than 7 to 110 mg · kg⁻¹. This element pollution originating mainly from the corrosion of copper wiring or roof elements. The zinc content in the analyzed samples is the highest among all the identified trace element and ranges from 61 to 677 mg · kg⁻¹. The main source of that metal contamination is the widespread use of zinc carbonate coated steel. This is confirmed by the results for samples located in the gutters for which the concentration of zinc reaches a value of 500-677 mg · kg⁻¹. The content of heavy metals in edifisols could be mainly explained by their inflow from construction materials and the impact of pollutants from the atmosphere.

HOW TO RECYCLE WASTES FOR SOIL CONSTRUCTION IN URBAN AREAS ?

Rokia Sarah^[1], Schwartz Christophe^[1], Vidal-Beaudet Laure^[2], Cannavo Patrice^[2], Guimont Sophie^[3], Renat Jean-Christophe^[3], Séré Geoffroy^[1], Damas Olivier^[4]

^[1]Laboratoire Sols et Environnement ~ Université de Lorraine, INRA ~ Vandoeuvre-lès-Nancy ~ France ^[2]UP Environnement Physique de la Plante Horticole ~ AgroCampus Ouest-Centre d'Angers ~ Angers ~ France ^[3]Valterra ~ Dépollution/Réhabilitation ~ Vandoeuvre-lès-Nancy ~ France ^[4]Plante et cité ~ Plante et cité ~ Angers ~ France

The development of green areas in cities requires the use of large quantities of imported agricultural soil. Furthermore, in the context of increasing urbanisation, high amounts of wastes and by-products are produced and are not systematically recycled as a resource. To preserve natural soil resources, we propose a strategy to use wastes and by-products as soil substitution materials during soil engineering. If organic wastes such as compost or sludge have already been studied in regard to their effects on soil properties, they have rarely been mixed together or with other by-products to get a fertile substrate. We have selected 10 contrasted materials i) representative for european wastes and ii) with physico-chemical characteristics adapted for fertile soil construction. This approach is developped in a national research program (Siterre) funded by the French Environmental Agency (ADEME). The wastes are characterised for their potential nutrient storage (C, N, P, K, Ca, Al, Mg, CEC), water storage and physical characteristics (bulk density). Among the 10 materials investigated, the organic ones (e.g. compost, paper mill sludge, green wastes) have contrasted characteristics - organic matter content ranging from 28.1 to 69.5 (w/w), and high water content. These characteristics being complementary to those of the mineral ones (e.g. rubble, bricks, track ballasts), we hypothesise that the mixture of both can produce a fertile substrate. Mixtures of wastes are determined with a decision support system to construct Technosols optimised for plant growth.

HYDRAULIC PROPERTIES AND AIR SUPPLY IN CEMETERY SOILS

Zimmermann Iris Maria^[1], Fleige Heinrich^[1], Horn Rainer^[1]

^[1]Institut für Pflanzenernährung und Bodenkunde ~ Christian-Albrechts-Universität zu Kiel ~ Kiel ~ Germany

Air supply and soil moisture have significant impact on the decay time necessary for complete decomposition of an interred body. Lack of oxygen may cause adipocere formation conserving the body and making the reuse of the grave after the regular resting time impossible. A study on cemetery soils in Germany was carried out, investigating the soil properties of 20 cemeteries and developing a quality rating system for cemetery soils. Special interest was taken in the changes in soil functions caused by excavation and refilling during the burial process. Air and water conductivity measurements in grave soils and monitoring of soil redox and moisture conditions in original graves on four cemeteries of different soil quality was realized. In order to test the effect of the application of quicklime on soil structure reamelioration and improvement of hydraulic as well as air permeability within the grave, moisture and redox conditions in newly excavated and refilled pits were measured continuously. Concerning the general structure and hydraulic as well as pneumatic conditions, very often a permeable refilled soil material overlaying the more compacted soil horizon at the bottom of the grave results in water ponding, less aerated conditions and lower redox potential values which reduce the decomposition speed or even prevent it. The improvement of the restructuring can be seen by a better aerated and more unsaturated soil if quicklime was added and a minor soil settling. Both the results and the rating system will be presented.

LET'S CULTIVATE OUR TOWN! INCREASING CITIZEN AWARENESS OF FOOD AND THE ENVIRONMENT THROUGH ORGANIC CULTIVATION OF ALLOTMENTS

Bretzel Francesca^{*[1]}, Pini Roberto^[1], Sparvoli Enzo^[1]

^[1]National Research Council ~ Institute for Ecosystem Studies ~ Pisa ~ Italy

The research aims to promote the sustainability of towns and cities through the awareness of the use of the soil in the cultivation of allotment gardens. The local council in Pisa provides all citizens that have allotments with guidelines for using organic techniques as best practices. "Gardeners" participate in training courses on nutrient cycles and soil fertility, vegetable varieties and organic cultivation, as well as how to make compost. Gardeners are surveyed through a specific questionnaire which is aimed at promoting such practices throughout the town of Pisa. We support gardeners in comparing their usual techniques with sustainable cultivation. Some local varieties of vegetable are cultivated both to promote knowledge of the local heritage and to preserve horticultural biodiversity. The administration departments of Tuscany and Pisa are co-funders of the projects.

MANAGING THE FUNCTIONALITY OF ANTHROPOGENIC SOILS

Lehmann Andreas^[1], Karl Stahr^[1]

^[1]Hohenheim University ~ Soil Science Institute ~ Stuttgart ~ Germany

Questions about the performance of technogenic soils could be motivated by at least three reasons: 1. How do urban or industrial soils contribute to the environmental quality in city regions 2. How could the relocation (digging and placing) of soils done without loss of functionality or even with increased functionality 3. How could the functionality of constructed soils be improved The processes taking place in disturbed soils with relevance to the functionality will be highlighted. The common praxis of creating urban soils, of relocating soils of constructing soils will be reported. Strategies to improve soils functionality by slight changes in soil management will be developed. Criteria to evaluate the loss, resp. the profit in soil functionality by relocation or construction of soils will be given.

S01.04-P -8

NEW DIAGNOSTIC CRITERIA FOR ANTHROPOGENIC SOIL CLASSIFICATION IN SLOVAKIA

Sobočka Jaroslava^{*[1]}, Bedrna Zoltan^[2], Balković Juraj^[2], Tatarková Zuzana^[2]

^[1]Soil Science and Conservation Research Institute ~ Dept. Of Pedology and Soil Survey ~ Bratislava ~ Slovakia

^[2]Comenius University ~ Dept. Of Pedology, Faculty of Natural Sciences ~ Bratislava ~ Slovakia

Anthropogenic soils can be found mostly in urban areas. Problem of adequate and correct description and classification of these soils occurs very often and results can be doubtful. In the new prepared version of anthropogenic soil classification in Slovakia some new diagnostics criteria were involved and applied for the anthropogenic soil classification. First two groups of anthropogenic soils were distinguished following reference groups in WRB 2006 (Anthrozem and Technozem). Both groups are differentiated by cultivated horizon(s) ("in-situ" developed soil material) and by anthropogenic horizon(s) ("ex-situ" developed soil material). Cultivated horizon is well-known described horizon in many scientific references. Anthropogenic horizon for Technozem is developed from the human transported material which origin is from the other ecological locality that adjacent area. Material can consists of various material (natural, technogenic or their mixing) with thickness = 50 cm. Artefacts are the second diagnostic property which presence authenticates the "artificial origin" of the soil. Natural material contains = 10 % artefacts; natural-technogenic 10-50 % artefacts; and technogenic = 50 %. If the surface horizon is e.g. arable land, we can distinguish the subsurface horizon. Most of such soils are appeared in urban areas due to building activities (machinery, recultivation processes, etc). In the soil survey anthropogenic transported layer is very simply recognizable in soil profile compared to natural horizons. In the contribution, there will be illustrated graphically individual basic soil types of Technozems with their subtypes. Also the basic schema of classification units in Slovakia will be involved.

POLLUTED SOILS IN CLOSE CONTACT WITH URBAN POPULATION OF A SEMI-ARID REGION, EXAMPLE CITY OF THERAN

Baharvand Mohammad^{*[1]}, Wolfgang Burghardt^[1]

^[1]University Duisburg-Essen ~ FK Biology, Soil Technology ~ Essen ~ Germany

Polluted Soils in Close Contact with Urban Population of a Semi-arid Region, Example City of Theran Mohammad BAHARVAND¹, Wolfgang BURGHARDT¹ ¹University Duisburg-Essen, Fk. Biology, Soil Technology, Essen, Germany; email: mo_baharvand@yahoo.com As example for soil investigations of a mega-city in Asia Teheran was chosen. It has a population size of 8, during the day of 10 millions inhabitants. The climate is arid to semi-arid. Due to the warm and dry climate public green areas, parks, and sidewalks are used by the population extreme intensively inside the city during most time of the year. From the way of life results an intensive contact of humans with the city soils. To get an idea of the characteristics and pollution with heavy metals of the soils involved park areas, children playgrounds, sidewalks and roadsides were sampled. The sampled soil profiles were 40 cm deep. Soil samples were taken from different depth and as volume samples In addition dust samples from sidewalks and streets were collected. The results showed a clear accumulation of pollutants in the southern and south eastern part of the city of Theran. We ascribe this to the prevailing direction of wind from the west and north, and the flow direction of sewage waters from north to south. Furthermore appear relationships between pollutants loads on streets, sidewalks and green areas.

SOIL ORGANIC CARBON STORAGE IN URBAN AREAS: UNDERESTIMATION OF STOCKS AND VARIATION AT A REGIONAL SCALE

Edmondson Jill*^[1], Mc Hugh Nicola^[1], Davies Zoe^[2], Gaston Kevin^[3], Leake Jonathan^[1]

^[1]University of Sheffield ~ Animal and Plant Sciences ~ Sheffield ~ United Kingdom ^[2]University of Kent ~ Durrell Institute of Conservation and Ecology ~ Canterbury ~ United Kingdom ^[3]University of Exeter ~ Environment and Sustainability Institute ~ Falmouth ~ United Kingdom

Soils are the foundations of the services provided by terrestrial ecosystems, and play a vital role in the storage of three quarters of the organic carbon sequestered from the atmosphere by plants. However, soil carbon stocks are being depleted by land-use changes globally, mainly through increased disturbance and cultivation. Urbanisation is an important contributor to land-use change, but its effects on soil organic carbon (SOC) have received little attention, particularly in densely built cities such as those in Western Europe. We present the first citywide SOC budget in Europe, for a typical mid-sized UK city (Leicester), including carbon storage to 1m depth based on measurements under the major greenspace areas and capped land under roads and paving. We found, contrary to assumptions currently applied to urban areas in national ecosystem carbon stocks recorded as part of the Kyoto Protocol obligations, the quantities of SOC in urban soils (13kg m⁻² over the entire city surface to 1m depth) exceeds that in adjacent agricultural landscapes. We are currently extending these studies across a 340km latitudinal gradient (55°46'N to 52°41'N) through the UK to establish (a) SOC storage variation across different urban areas (b) variation in urban SOC storage in relation to soil type and (c) variation in urban SOC storage in relation to latitude. These data will help to refine national scale estimates of SOC for urban areas, which to date appear to have been seriously underestimated, particularly in highly urbanized areas.

S01.04-P -11

SUBSURFACE URBAN HEAT ISLAND INVESTIGATIONS IN OBERHAUSEN, GERMANY

Püllen Helene*^[1], Kuttler Wilhelm^[1]

^[1]University of Duisburg-Essen ~ Biology - Applied Climatology and Landscape Ecology ~ Essen ~ Germany

The role of soils in the urban environment is manifold, concerning the thermal aspect ambivalent: on the one hand soils with sufficient moisture content possess a natural cooling potential, on the other hand they are energy reservoirs replenished by human activity. The well known urban heat island (UHI) therefore is not only a phenomenon of the atmospheric boundary layer of cities but also exists in the near and far underground of sealed areas. Dependent on the time of year subsurface urban heat island intensities in depths of one to two meters can reach up to 7 K (daily mean) in comparison to the same depth in the rural environment. In the city of Oberhausen, NRW, Germany, spatially and temporally highly resolved measurements of soil temperature, soil moisture and ground heat flux (01.08.2010 – 31.07.2011) allow a good insight into the temperature- and heat storage distribution in dependence of urban thermal climate zones and soil types. It is shown that heavily modified and sealed sites in proximity of the city center display greater energy content than natural sites most of the year. Using this additional energy serves as adaptation and mitigation strategy at the same time: on the one hand the existing heat will be used on the other hand energy savings contribute to mitigating climate change. Calculations of using this underground energy will be given for different urban climate zones. Also the importance of soil moisture for cooling efficiency will be stressed.

S01.04-P -12

**TYPES, AMOUNT AND POTENTIAL OF URBAN SOILS FOR ORGANIC MATTER
ACCUMULATION**

Burghardt Wolfgang*^[1]

^[1] University Duisburg-Essen ~ Soil Technology/Angewandte Bodenkunde, FK Biology ~ Essen ~ Germany

The accumulation of organic carbon in urban soils is only marginal described (Burghardt 2001, Burghardt and Niggemeyer 2002). Compared to rural areas soils of urban areas have a wide spectra of types of soil formation and morphology which have are characterized by very distinct distribution of carbon contents in the profile and distinct amounts of stored carbon. The presentation will show the carbon enrichment types and the amount of stored carbon of (1)mainly on the surface occurring carbon accumulation of urban soils of different age and land use, (2)the deep accumulation by compost management of Hortisols, Nekrosols and deposited (allochthonous) materials Technosols, (3) soils from buried horizons with several carbon accumulation layers, and (4) soils developing from dust rich in carbon such as sand and gravel layers with voids filled with dust. Carbon storage in soils is a long lasting process starting with zero carbon content until its maximum is achieved after many years. Urban soils are mostly young soils. That means that they have a high capacity to store organic carbon with time. This effect can be observed even in relictic already organic matter containing soils. This knowledge about the way of organic matter accumulation can be used for targeted organic matter management in urban soils. It should be part of the environmental policy of city administrations.

S01.04-P -13

WHAT POTENTIAL OF BY-PRODUCTS FOR AGRONOMIC USE IN URBAN AREAS?

Rokia Sarah^{*[1]}, Schwartz Christophe^[1], Vidal-Beaudet Laure^[2]

^[1]Laboratoire Sol et Environnement ~ INRA-Université de Lorraine ~ Vandoeuvre les Nancy ~ France ^[2]AGROCAMPUS OUEST-Centre d'Angers, Angers ~ UP Environnement Physique de la Plante Horticole ~ Angers ~ France

The development of green areas in many cities requires the import of soil in large quantities. Besides, in the context of urbanization increase, by-products get to be produced in high amounts and do not always present re-use opportunities. As a result, the strategy is to recycle by-products for a use as soil substitution materials and to preserve the soil resource. If some organic materials such as compost or sludge have already been studied in regard to the effects of their addition on soil properties, they have rarely been mixed together or with other by-products to get a fertile substrate. Therefore, in this study, we focus on five organic materials and five mineral ones. The potential nutrient storage (C, N, pH, CEC, Al, Ca, K, Mg, P₂O₅) of each material has been evaluated and measurements of water storage and physical characteristics, are also in acquisition. Among the materials investigated the organic ones such as compost, paper mill sludge and green wastes show high organic matter content ranging from 28.1 to 69.5 (w/w), and high water content ranging from 40 to 80 % at field capacity. When mixed with the organic ones the mineral materials like bricks are expected to enable the achievement of a mechanical stable mixed substrate. Thus the aim is to complement the low potential of materials from demolition with the high agronomic potential of organic wastes. Ultimately, this characterization will help to produce a modelling tool to lead the suitable mixture of materials for urban plantations.

2012 NATIONAL COOPERATIVE SOIL SURVEY WORK PLANNING CONFERENCES – NATIONAL COLLABORATIVE RESEARCH AGENDA FOR EMERGING ISSUES

Levin Maxine^{*[1]}, West Larry^[3], Cavallaro Nancy^[2], Reinsch Thomas^[1], Benedict Paul^[1]

^[3]USDA-NRCS/NSSC ~ Lincoln ~ Nebraska ~ United States ^[1]USDA-Natural Resources Conservation Service ~ Soil Survey Division ~ Washington DC ~ United States ^[2]USDA-NIFA ~ National Institute of Agriculture ~ Washington, DC ~ United States

The US National Cooperative Soil Survey (NCSS) National Conferences convene to discuss and develop solutions to issues of national concern to the National Cooperative Soil Survey. Participants of the NCSS include representatives from the land-grant universities experiment stations, NRCS, USFS, BLM, BIA, EPA, USFWS, SSSA, and tribal colleges. Other interested foreign and domestic groups such as lead scientists from Canada, Mexico and other cooperative countries are invited to participate. Committees convene each year at the regional and national meetings to establish a collaborative work plan to address grassroots issues as well as national priorities under the national umbrella of the NCSS. The Research Agenda Committee has established a collaborative work plan to address emerging issues. Priorities are divided into 3 categories: Short-Term Priorities, Global Priorities and National Applications. Short-Term Priorities are focused on soil change, new technology, ecological site descriptions, subaqueous soils, landscape hydraulic function and hydrogeology, gypseous and salt-affected soils and NCSS database harmonization. Global Priorities are focused on scaling/extrapolation, landscape-scale carbon processes and accounting, integration of soil organic carbon and land use, adaptation and prediction of soil CO₂ sequestration, soil ecosystem services, soil function, and development and testing of decision support tools. The final category of Application of Soil Survey Data includes the integration of carbon and land use data into conservation planning and related activities, data validation and urban/suburban interpretations. This paper briefly overviews highlights of the 2012 NCSS research agenda with specific examples

CHARACTERISTICS AND CLASSIFICATION OF URBAN SOILS IN THE CITY OF SISAK, CROATIA

Husnjak Stjepan^{*[1]}, Rubinic Vedran^[1], Halamic Josip^[2], Sorsa Ajka^[2], Vrbek Boris^[3]

^[1]University of Zagreb, Faculty of Agriculture ~ Soil Science ~ Zagreb ~ Croatia ^[2]Croatian Geological Survey ~ - ~ Zagreb ~ Croatia ^[3]Croatian Forest Research Institute ~ - ~ Zagreb ~ Croatia

City of Sisak is characterized by continuity of urban living for more than 2000 years. Significant portion of its urban area is occupied by land used for parks, playgrounds, smaller agricultural plots, etc. The aim of this paper was to present the characteristics and classification of urban soils in Sisak, according to Croatian Soil Classification (CSC) and WRB, on the basis of three soil profiles. Urban soils in Croatia were mainly systemized into the class of Technogenic soils, as Deposol soil type. However, in some of those soils, it is possible to detect evidence of ongoing pedogenetic processes, resulting in further soil development. In two of the three investigated soil profiles, pedogenesis led to formation of a humus accumulative horizon. Since in CSC this horizon is diagnostic for the class of Humus accumulative soils, we classified these soils as Rendzinas on deposited land material. According to WRB, one of these soils was classified as Urbic Technosol (Calcaric, Humic, Skeletic) and the other as Endostagnic Regosol (Hypereutric, Siltic, Transportic). In only one of the three investigated soil profiles, the organic matter in the surface horizon has not accumulated mainly as a result of natural pedogenesis. This profile featured a nylon film below the artificially formed humus rich surface layer, and was classified as Deposol on land material, according to CSC, or as Linic Technosol (Calcaric, Ruptic, Siltic), according to WRB. Finally, the recommendations for division of Deposols, as well as Rendzinas on land material, to lower level units are given.

CLAY MINERALS IDENTIFICATION IN SOIL PROFILES DEVELOPED ON RHYODACITE AND BASALTE IN SOUTHERN BRAZIL

Radtke Leopoldo*^[1], Caner Laurent^[1], Inda Junior Alberto^[2], Vignol-Lelarge Maria Lidia^[3], Mexias André^[3], Edson Campanhola Bortoluzzi^[5]

^[1]Université de Poitiers ~ HydrASA ~ Poitiers ~ France ^[2]UFRGS ~ Department of Agronomy ~ Porto Alegre ~ Brazil

^[3]UFRGS ~ Geosciences department ~ Porto Alegre ~ Brazil ^[4]Universidade de Passo Fundo ~ Agronomy Department ~ Passo Fundo ~ Brazil ^[5]Universidade de Passo Fundo ~ Agronomy Department ~ Passo Fundo ~ Brazil

The Rio Grande do Sul state in southern Brazil is intensively cultivated due to its subtropical climate. Clay mineralogy and especially 2:1 clay minerals plays a key role in soil fertility by contribution to cation retention in these soils with low cation exchange capacity. Two soil profiles developed on basalt and on rhyo-dacite were sampled for their different horizons from the surface to the bedrock. Total element analysis, physico-chemical properties and clay mineralogy identification were performed. X-ray diffraction of Ca-saturated clay samples was performed on air-dried state (AD) at room temperature and following ethylene glycol solvation (EG). K-saturated clay samples were recorded at AD, 110°C, 300°C and 550°C. Samples were also treated with sodium tricitrate (Tamura treatment) in order to identify hydroxy-interlayered clay minerals. The soils present a low CEC and the exchangeable cations are dominated by Al. The clay mineral assemblage is formed with kaolinite and a non-swelling 2:1 clay mineral in the surface horizons. Gibbsite is also present in the soil derived from rhyo-dacite. The incomplete collapse following Tamura treatment, K-saturation and heating allowed identifying this clay 2:1 mineral as hydroxy-interlayered vermiculite (HIV). The presence of HIV in the surface horizons can be linked to acidic conditions favoring the accessibility of Al to interlayer space of 2:1 clays minerals. The proportion of interlayer Al in the 2:1 clay minerals controls at least partly the CEC of the soils and thus cation retention (K, Ca). This study shows that despite strong weathering these soils present 2:1 clay minerals.

COMPARISON OF SOIL TAXONOMY AND WRB FOR DESCRIPTION OF SOIL PROPERTIES IN ARID AND SEMIARID REGIONS OF CENTRAL IRAN

Salehi Mohammad Hassan*^[1], Bahmani Morteza^[1]

^[1]Shahrekord University ~ soil science ~ shahrekord ~ Iran, Islamic Republic of

One of the main reasons of soil classification systems is to identify the differences of soil properties for management purposes. In this study, the efficiency of American and WRB soil classification systems were compared in order to describe soil physical, chemical and mineralogical properties in arid and semiarid regions of central Iran. Khatoon Abad and Mobarekeh plains as arid regions and Koohrang and Shahrekord plains as semiarid regions were selected. Then, representative pedons of each plain were chosen from 16 excavated pedons and soil samples were taken from genetic horizons to determine soil classification. Results showed that soil orders of both Koohrang and Khatoon Abad plains are vertisols according to American soil classification system whereas these soils are classified as cambisols and calsisols, respectively based on WRB system. On the other hand, both Mobarekeh and Shahrekord soils are classified as calcisols in WRB system whereas these soils are classified as aridisols and inceptisols, respectively according to American soil taxonomy. None of soil classification systems could show the existence of gypsum in horizons lower than 100 cm for Mobarekeh soil. Clay mineralogy indicates that smectite is the dominant clay mineral in Koohrang soil as explains well at family level of American soil classification system. Results of soil classification at lower levels suggest that WRB has somewhat higher efficiency than American soil classification system for description of the soils in the study area.

CRYSTALLINE IDIOMORFISM LIKE NEOFORMATION SIGN OF QUARTZ GRAINS IN MEDITERRANEAN SOILS

Márquez-Crespo Rocío^[1], Bech Jaume^{*[4]}, Martín-García Juan Manuel^[3], Delgado Gabriel^[3], Delgado Rafael^[3]

^[1]Universidad de Granada ~ Centro de Instrumentación Científica ~ Granada ~ Spain ^[2]Universidad de Barcelona ~ Facultad de Biología ~ Barcelona ~ Spain ^[3]Universidad de Granada ~ Edafología y Química Agrícola ~ Granada ~ Spain ^[4]Universidad de Barcelona ~ Biología Vegetal ~ Barcelona ~ Spain

In studies with scanning electron microscopy (SEM), of the light fine sand fraction of selected Mediterranean soils (Chromi-Leptic Luvisol, Delgado et al., 2003; Typic Calcixeroll and Fluventic Haploxeroll, Márquez-Crespo, 2003), we have recognized quartz grains that can be described as near-idiomorphic crystals. They show crystalline forms with faces, edges and vertices, well defined. In quartz crystals is common the association of two rhombohedra faces, $r \{1011\}$ and $z \{0111\}$, which generate a pseudobipyramid, and the prism face $m \{1010\}$. In some of these quartz grains have even been observed growth striations and some fine granular films on its surface, possibly of colloidal silica (Delgado et al., 2003). It is an unequivocal symptom of the process of crystal growth. The soil solution of some of the horizons of these soils (for example Ah, Typic Calcixeroll), where appear the described morphologies of quartz grains, has a concentration of dissolved silica that exceeds the saturation levels to mean annual soil temperature (Rimstidt, 1997). These evidences allow establishing the mineral neoformation as a plausible hypothesis in these soils. Thus, quartz grains grow to develop the near-perfect crystalline forms observed. The detected process has been classically described in highly developed soils like tropical soils (Whitehouse, 1940; Eswaran, 1970; Flageollet, 1981) and in some mediterranean soils (Torcal Tello-Sainz and Ripa, 1992). With our results the paradigm of the quartz stability in Mediterranean environments is questioned.

DEVELOPMENT OF SOIL EVOLUTION AFTER AFFORESTATION OF AGRICULTURAL LANDS IN GLACIGENIC TILL SOILS OF BOREAL-NEMORAL AREA

Kasparinskis Raimonds^{*[1]}, Nikodemus Olgerts^[1], Kukuls Imants^[1], Rolavs Nauris^[1]

^[1]University of Latvia ~ Faculty of Geography and Earth Sciences ~ Riga ~ Latvia

Land use history determines the soil-forming processes, morphology, physical and chemical properties. Considering that afforestation of agricultural lands is taking place in Europe, it is important to clarify development of soil-forming processes after afforestation. This information is significant for the interpretation of land use history, improvement of soil mapping and modelling of its spatial distribution, as well as to develop proposals for land management. The afforestation impact on soil properties and processes were investigated in glacial till soils in the central part of Latvia. Development of podzolization process is observed in first 70 years after afforestation, as indicated by morphological features (genesis of secondary E and B horizons), decrease of pH_{KCl} value, changes of amorphous aluminium (Al_o) and iron (Fe_o) content in soil horizons. Afforestation also affects the content of soil organic carbon. The major part of organic carbon accumulates in O horizon of forest soils. In investigated forest soils the thickness of O horizon (mull and moder type) differs from 1 to 10 cm, and this thickness does not depend on the age of forest land, but is affected by predominant vegetation as well as chemical composition of mineral topsoil. In general, more intensive biological cycle of organic matter and relatively slow development of podzolization are observed in afforested agricultural lands in comparison to older forest lands in glacial till deposits.

ENDOLITHIC PEDOGENESIS AND ROCK VARNISH ON GRANITOIDES IN EAST ANTARCTICA

Mergelov Nikita*^[1], Goryachkin Sergey^[1], Shorkunov Ilya^[1], Zazovskaya Elia^[1], Cherkinsky Alexander^[2]

^[1]Institute of Geography, Russian Academy of Sciences ~ Soil Geography and Evolution Lab ~ Moscow ~ Russian Federation ^[2]University of Georgia-Athens ~ CAIS ~ Athens ~ United States

Rock varnish and endolithic organisms being quite widespread phenomena on Earth are very well studied apart however their interaction and possible cogenesis had never been particularly explored. Endolithic organisms – are important primary producers in the ice-free areas (oases) of Antarctica (Friedmann, 1982) inhabiting structural cavities in the superficial rock interior. The other common feature of Antarctica oases is the red-brownish colour of solid rocks (granites, gneisses etc.) which is traditionally attributed to the presence of Fe-Mn-coatings on the surface (rock varnish). Our explorations showed that such system as “endolithic organisms-granitoid rock-weathering products” has all features to be denominated as soil: (1) rock layer exposed to external abiotic factors; (2) this layer is inhabited by living organisms synthesizing and decomposing organic matter (OM); (3) induced by biotic and abiotic factors initial lithomatrix is transformed in situ, transformation products are retained and/or taken away, vertical heterogeneity (microprofile) is formed. Organo-mineral horizons of endolithic soil contain 0,2-3,3% C and 0,02-0,47% N. ¹⁴C mean residence time of OM reaches 480±25 BP. Major pedogenesis products – numerous Fe-C-Si-Al-S-Cl-Ca-Mg-containing bio-coatings which cover cavities inside the rock. Main binding material – amorphous silica and Al with incorporated bio-mineral detritus. C content – 10-50%. SEM morphology and elemental composition of coatings correspond very well to those observed in varnish on rock day surface. Thus, certain types of rock varnish could be the products of endolithic pedogenesis exposed after exfoliation and transformed by external factors. This hypothesis doesn't claim to explain all rock varnishes (e.g. formed by accretion).

EUROPEAN HUMUS FORMS REFERENCE BASE

Zanella Augusto^[1], Englisch Michael^[3], Sartori Giacomo^[4], Gardi Ciro^[5]

^[1]University of Padua ~ TeSAF ~ Padova ~ Italy ^[2]Bundesamt für Wald, Unit Site and Vegetation, ~ Forest Ecology and Soil ~ Vienna ~ Austria ^[3]Bundesamt für Wald, Unit Site and Vegetation ~ Forest Ecology and Soil ~ Vienna ~ Austria ^[4]Museo Tridentino di Scienze Naturali ~ Via Calepina 14 ~ Trento ~ Italy ^[5]European Commission - DG JRC ~ Institute for Environment & Sustainability (IES) ~ Ispra ~ Italy

From 2003 on, a panel of experts in humus and humus dynamics (Humus group) has been working on a European Humus Form Reference Base. It roots deeply in national humus form classification systems, while a lot of work had to be done in order to standardize definitions and approaches. Some important goals have been reached, in order to share data and experiences: a) the definition of specific terms; b) a description of 15 types of diagnostic horizons and c) of 10 basic humus forms references; d) the subdivision of each main reference in 2-4 subunits; e) the elaboration of a general European Humus Form Reference Base(http://hal-agroparistech.archives-ouvertes.fr/docs/00/56/17/95/PDF/Humus_Forms_ERB_31_01_2011.pdf); f) the publication of the scientific significance of this base of classification as an article [A European morpho-functional classification of humus forms. *Geoderma*, 164 (3-4), 138-145]. The classification will be updated every 2 years and presently the Humus group is assessing biological (fungi, bacteria, pedofauna), physical (air temperature, rainfall) and chemical (pH, nutrients, quality and quantity of humic compounds...) factors which characterize basic humus forms and their varieties. The principles of the classification, the diagnostic horizons and humus forms main references are presented at the 4th International Congress of ECSSS with the aim to stimulate the participants' curiosity. Interested people are invited to test the classification system in various environments and collaborate with the Humus group. Critical observations and field data/assessments are welcome as every other suggestion which can help in elaborating the 2013 version of the European humus forms classification.

FORMATION AND EVOLUTION OF INITIAL SOILS IN A LANDSLIDE TERRAIN – A CASE STUDY FROM THE SUDETES (SW POLAND)

Kacprzak Andrzej^[3], Migon Piotr^[2], Musielok Lukasz^[3]

^[1]Institute of Geography and Spatial Management ~ Department of Pedology and Soil Geography ~ Kraków ~ Poland

^[2]University of Wrocław ~ Department of Geography and Regional Development ~ Wrocław ~ Poland ^[3]Jagiellonian University ~ Institute of Geography and Spatial Management ~ Kraków ~ Poland

Due to its specific geological structure i.e. interbedding of Paleozoic volcanic rocks and sedimentary sandstones and shales the area of Góry Kamienne (Central Sudetes) is susceptible to mass-wasting processes. A large number of forms resulting from a range of processes (landslides sensu stricto, flowslides, rockfalls) and of supposedly various age can be observed. Mass wasting activity can be a factor directly controlling the structure of soil cover at certain locations. Depending on the bedrock (crystalline or sedimentary), age and nature of mass movements different soils and structures of soil cover have developed in the investigated area. However, the main characteristic is a large variability of soils in a relatively small area. Most mapping units, even at large mapping scales, are complex associations of soil units with unique properties. The most typical and widespread are various units of Leptosols and Regosols, undergoing further evolution towards specific units of Histosols, Umbrisols and Cambisols. Analysis of soil properties such as the content and distribution of organic carbon, development of soil structure and profile horizonation may be used as a useful tool to estimate the relative age of different generations of mass movements. To a limited degree it may also be used to infer absolute age of landslides ranging from inactive Pleistocene forms, through early Holocene to those which may have formed as recently as a few hundred years ago.

GLOBAL AND LOCAL PEDODIVERSITY- RESULTS FROM ARID REGIONS OF SOUTHEAST IRAN

Khademi Hossein*^[1], Jafari Azam^[1], Ayoubi Shamsollah^[1]

^[1]Isfahan University of Technology ~ Soil Science ~ Isfahan ~ Iran, Islamic Republic of

A geomorphic hierarchical downscaling method was used to decompose the forms and processes forming the landscapes and their subdivisions in an arid region of southeast Iran. This paper discusses the study of pedodiversity in two ways (1) based on the global scale using the digital soil map and (2) the local pedodiversity based on geomorphic hierarchical downscaling method. The calculation of diversity indices were carried out according to taxonomic categories of order, suborder, great group, and subgroup. Using the feed forward back-propagation algorithm, a neural network was trained for prediction of the digital soil map in each category level. The results showed that the diversity indices increase from soil order to soil subgroup at global and local scales. Therefore, the greater number of soil units or higher density of the soil map, the higher diversity at the subgroup category. An increase in K-entropy of soil and landscape confirms the hypothesis of soil divergence evolution, whereby differences in initial conditions or local perturbations, and dynamic in stability appear to have produced more variable soils and landscapes in the study area. The global diversity obtained based on soil map, so diversity measures depend on the density of the soil map. Therefore, higher soil diversity was achieved with greater density of different soil units. It was observed that areas with more detailed soil mapping units exhibit the largest pedodiversity and it was concluded that the measure of pedodiversity depends amongst others on the detail of the soil survey in an area.

INFLUENCE OF CYANIDE ON GRANITE DISSOLUTION

Wongfun Nuttakan^{*[3]}, Brandl Helmut^[2], Plötze Michael^[4], Furrer Gerhard^[3]

^[1]Institute of Biogeochemistry and Pollutant Dynamics ~ Department of Environmental Systems Science ~ Zurich ~ Switzerland

^[2]University of Zurich ~ Institute of Evolutionary Biology and Environmental Studies ~ Zurich ~ Switzerland

^[3]ETH Zurich ~ Institute of Biogeochemistry and Pollutant Dynamics ~ Zurich ~ Switzerland ^[4]ETH Zurich ~ Institute for Geotechnical Engineering ~ Zurich ~ Switzerland

*In the course of glacier retrieval and loss of permafrost, rocks become loose and are subjected to erosion. This development can be limited or prevented only if soil and vegetation cover is developed rapidly. Weathering is seen as provision of nutrients that are required by the pioneering life in deglaciated alpine areas, where soil development is at its initial stage. Living organisms modify their local environment by various exudates, including cyanide. Cyanide formed in the prebiotic soup is considered as the oldest lixiviant. Several cyanide-producing bacteria enhance elemental release by extensive colonisation of granite surfaces. We studied the effect of cyanide on granite dissolution in batch experiments under controlled conditions. Rocks, weathered stream sediments and bacterial strains were obtained from the Damma glacier area (Central Alps, Switzerland). Abiotic experiments in absence of cyanide show an increase of released Fe with decreasing pH (0.02 $\mu\text{mol/L}$ at pH 7 and 2.56 $\mu\text{mol/L}$ at pH 5). Cyanide, conversely, appears to enhance dissolved Fe concentration in particular with increasing pH (3.96 $\mu\text{mol/L}$ at pH 5 and 32.62 $\mu\text{mol/L}$ at pH 7). This suggests that elevated concentration of deprotonated cyanide become more important for the formation of Fe-cyanide complexes. Biotic influence of granite dissolution was studied under nutrient-limited conditions. Preliminary results show that *Pseudomonas* species exhibit a relatively high potential to dissolve granite material, in particular *P. fluorescens*, which is known as an effective cyanide producer.*

INITIAL HUMUS ACCUMULATION ON THE EARLY EARTH – COULD LICHENS BE RESPONSIBLE?

Zavarzina Anna*^[1]

^[1]Institute of Paleontology RAS ~ Ancient organisms ~ Russian Federation

Soil development is a major process in transformation of land surface into habitable environment. Most soils in the modern biosphere are the product of higher plants. But what was before their appearance on land? Which vegetation on the early Earth could produce first humified soils? About 90% of soil humus is represented by recalcitrant humic substances (HS) and their complexes with dispersed minerals. HS are mainly formed from various polyphenols which undergo oxidative transformation in presence of fungal laccases and peroxidases or soil minerals and then spontaneously couple with nitrogenous compounds, carbohydrates etc. Thus, ultimate precondition for the formation of modern-type organic-mineral soils is presence of biota which serves as a source of phenolic compounds. The earliest steps in land colonization might be linked to the algo-myco-bacterial communities which moved from inland freshwater bodies to the porous wet ground (GA Zavarzin, in press). Representatives of algo-myco-bacterial world formed lichenized consortia as adaptation to severe conditions on the unshaded land surface. Algae and cyanobacteria lack phenolic compounds. In present work the role of lichens as possible organisms responsible for the early humification process will be discussed. Lichens are often pioneers on rocky surfaces and are well known for their high stress-tolerance and participation in mineral weathering. We have recently discovered that lichens produce laccases and tyrosinases as well as noticeable amounts of soluble phenolic compounds. Thus lichens can contribute to primary accumulation of soil organic matter via products of thalli decomposition, leached-off phenolic compounds and enzymes that catalyze humification.

INNER OUTWASH PLAINS OF NORTH-EASTERN POLAND – THE SPECIFICITY OF SOILS AND FORMATION CONDITIONS

Bieniek Arkadiusz*^[1]

^[1]University of Warmia and Mazury in Olsztyn ~ Soil Science and Soil Protection ~ Olsztyn ~ Poland

Scandinavian ice sheet had the maximum reach in Poland remaining young glacial relief. Its scope is marked mainly by geomorphologic criteria: “freshness” of the relief, lake channels, frontal moraines and outwash plains. Inner outwash plains (interglacial) were formed as a combined glacifluvial system or a closed area in a following combination: flow through channel, outwash plain, area of ice dammed lakes origin. The research was carried out on a route of outwash plains in Lyna river valley as well as forested and agriculturally used closed outwash plains areas. The route of outwash plains begins near Sepopol and runs south-west. Near Laniewo, its origin is different. It was formed as a result of discharge of glacial streams to the south. Its width reaches 12 kilometers and the most narrow part is approximately 500 meters. It finishes its run near Olsztyn making a wide fan in the south. It is a marginal zone of Pomeranian phase of Vistulian glaciation. The study comprises site conditions as well as analyses of pedo- and lithogenetic processes in these areas. Soil-forming processes occurring in homogenous lithogenetic area, which is closed by waters flowing from melting glacier were also analysed. The specificity of formed soils, including morphology, physical and chemical properties and forms of iron, enabled to estimate the soil-forming processes. Particularly important are the contact zones between the outwash plain, moraines and area of ice-dammed lakes origin. Moreover, the differences in trophism of soils of outwash plains were studied.

LATE QUATERNARY PALAEOECOLOGICAL CHANGES IN EASTERN ISFAHAN, IRAN, AS REVEALED BY STABLE ISOTOPE GEOCHEMISTRY OF PEDOGENIC CARBONATES

Bayat Omid*^[1], Amundson Ronald^[2], Khademi Hossein^[1], Karimzadeh Hamid Reza^[3]

^[1]Isfahan University of Technology ~ Department of Soil Science ~ Isfahan ~ Iran, Islamic Republic of ^[2]University of California ~ Division of Ecosystem Sciences ~ Berkeley ~ United States ^[3]Isfahan University of Technology ~ Department of Natural Resources ~ Isfahan ~ Iran, Islamic Republic of

Only a few studies have been carried out on the relationship between geomorphic surfaces, isotope geochemistry of pedogenic carbonates and Quaternary palaeoecological changes in arid lands of Iran. The aims of this study were to investigate the pedogenic carbonates properties in different geomorphic surfaces of an alluvial fan in eastern Isfahan and ecologicological and climatic conditions during evolution of this surfaces. Three pedons on geomorphic surfaces of an alluvial fan were selected and studied. Paleovegetation of study area was identified using signals from carbon isotopes in pedogenic carbonates. The results indicate that the expansion of C4 plants occurred during periods with low $d18O$ (glacial periods). It seems that the decrease in atmospheric carbon dioxide concentration during glacial periods was the main factor responsible for the expansion of C4 plants in the region. These results are in corroboration with palynological investigations in western Iran. It also appears that the changes in atmospheric carbon dioxide and other climatic factors significantly influenced the palaeoecology, landscape stability, soil erosion and pedogenic development of studied pedons. This is particularly important because of an increase in greenhouse gases and global warming in recent years that can affect ecological changes, desertification and soil erosion in arid regions of central Iran.

LONG-TERM EFFECTS OF ORGANIC AMENDMENTS ON PLANT AND SOIL MICROBIAL COMMUNITY DEVELOPMENT FOLLOWING OPEN PIT MINING IN THE CANADIAN BOREAL FOREST

Hahn Aria*^[1], Quideau Sylvie^[1]

^[1]University of Alberta ~ Renewable Resources ~ Edmonton ~ Canada

In natural areas, forest floor layers overlying mineral soils contribute to ecosystem recovery after disturbance. The application of forest floor materials as an organic amendment to reclaimed areas has been shown to result in a greater native revegetation response compared to sites reclaimed with a peat amendment. However, the influence of native vegetation on early stage soil microbial community development is not yet fully understood. This study describes the combined effects of organic amendment, moisture, and plant cover on soil microbial community development in a long-term (seven year) field experiment. Phospholipid fatty acid analysis was used to characterize and compare soil microbial community composition and development on reclaimed and natural forest sites. Additionally, we conducted a laboratory moisture manipulation experiment. The use of salvaged forest floor material as an organic amendment resulted in a greater percent cover of upland vegetation and placed the soil microbial community on a faster trajectory towards ecosystem recovery than did the use of a peat amendment salvaged from nearby lowlands. The soil microbial composition within the reclaimed sites exhibited a greater response to changes in moisture than did the soil microbial communities from natural forest sites. Our research shows that the use of native organic amendment (forest floor) on reclaimed sites, and the associated establishment of native vegetation, promotes the development of soil microbial communities more similar to those found on natural forest sites. Additionally, natural soil microbial communities may be more resistant to changes in soil moisture than those found on reclaimed sites.

PHYSICAL, CHEMICAL AND MINERALOGICAL CHARACTERISTICS OF VERTISOLS OF THE OCEANIC ISLAND OF FERNANDO DE NORONHA – BRAZIL

Adriano Marques Flávio^[1], Rosas Ribeiro Mateus^[2], Severino De Souza Júnior Valdomiro^[2], Da Silva Souza Regilene Angélica^{*[2]}, Wanderley Fernandes Lima José Fernando^[2], Santos De Sousa Juliet Emilia^[2]

^[1]Brazilian Agricultural Research Corporation ~ Embrapa Solos ~ Recife – Pernambuco ~ Brazil ^[2]Federal Rural University of Pernambuco (UFRPE) ~ Soil Science Department ~ Recife – Pernambuco ~ Brazil

The oceanic islands due their geographical isolation, often show a unique biodiversity, which have received great attention from the scientific community because of their environmental importance. In Brazil, due the extent of its coastline, several oceanic islands can be found, among them, the Fernando de Noronha (FN) archipelago, located at 345 km far from the Brazilian coast. The Vertisols developed in FN are strongly influenced by the parent material of volcanic or sedimentary origin, and by the dry tropical climate with great oceanic influence, but were still little studied. This work aimed to study Vertisols of common occurrence in FN, formed from different parent materials, emphasizing their physical, chemical and mineralogical characteristics. The study was performed in five soil profiles, representatives the soil mapping units, reflecting changes in parent material and topography. Physical, chemical and mineralogical analyses were carried out in the collected soil profiles. The Vertisols were developed on the main island central plateau, related with slightly depressed areas and have poor drainage, and are characterized by very clayey texture. Sum of bases and base saturation were high, with increasing the values of exchangeable sodium in subsurface horizons, showing sodic or solodic character, according to Brazilian System of Soil Classification. The available phosphorus values were very high. The mineralogy of the silt fraction was uniform in all horizons, indicating similarity of the parental materials. The dominant minerals in this fraction were: kaolinite, feldspar, mica and pyroxene. In clay fraction, the dominant minerals were: smectites, micas and kaolinite.

S02.01-P -17

PROPOSAL FOR AN INTERNATIONAL SOIL PARENT MATERIAL CLASSIFICATION AS A BASIS FOR RE-INTERPRETING DIGITAL GEOLOGICAL DATA FOR SOIL MAPPING

Schuler Ulrich^{*[1]}, Rainer Baritz^[1], Jan Willer^[1], Harald G. Dill^[1]

^[1]Federal Institute for Geosciences and Natural Resources ~ B 2.2 Spatial Information Soil and Water ~ Hannover ~ Germany

In the frame of the eSOTER project new methods for soil science relevant delineation of terrain units using GIS models are developed. This is largely based on digital terrain and lithology data. Emphasis is here on the development of a lithological classification thought to revise the existing FAO one, in order to ease subsequent digital soil mapping. With these activities, the BGR also supports the global environmental monitoring system GEOSS (task "global soil data"). The existing parent rock classification systems have several shortcomings in the way that they are often inconsistent, only locally applicable, incomplete, and contain not defined terms. The proposed classification consists of two parts. In the first part the parent rock properties are described according to the consolidation degree, the geochemical character, and the major rock type which serve as indicators for direction and extent of soil formation. In the second part, surface processes related to the genesis of the parent rock are described. These processes are specified into ongoing and relictic ones. The reason for the latter distinction is that it allows for a separation of rather young and more developed soil formation. The proposed classification can be used to generate a harmonized soil parent material map for Europe, which in turn can serve as an important data layer in digital soil mapping.

RECOVERY OF BIOLOGICAL SOIL CRUSTS AFTER DISTURBANCE ALONG A RAINFALL GRADIENT IN THE TRANSITION ZONE BETWEEN THE NW NEGEV, ISRAEL AND THE PALESTINIAN GAZA STRIP

Steckenmesser Daniel^{*[1]}, Sylvie Drahorad^[1], Vincent Felde^[1], Yasser El-Nahhal^[2], Jamal Safi^[2], Peter Felix-Henningsen^[1]

^[1]Justus Liebig University ~ Institute for Soil Science and Soil Conservation, Research Centre for Biosystems, Landuse and Nutrition (IFZ) ~ Giessen ~ Germany ^[2]Environmental Protection and Research Institute (EPRI) ~ EPRI ~ Gaza ~ Palestinian Territory, Occupied

Sandy soils of the semiarid dune fields of the Palestinian Gaza Strip and the Israeli western Negev are covered by biological soil crusts (BSC), which stabilize the surface and prevent desertification. Landuse of these fragile ecosystems induces destruction of the BSC and initiates desertification. To investigate the recovery of BSC after disturbances recovery plots were monitored for a 3 year period along a rainfall gradient (90 mm a⁻¹ to 170 mm a⁻¹). The BSC was sampled in two depths (0 – 2 mm, 2-30 mm) and the underlain topsoil up to 10 cm was collected. Samples were analysed on their concentrations of calcium carbonate, water soluble nitrogen, cations and anions and particle size distribution. The amount of salts was calculated based on Simon et al. (1995). After one year of recovery a stabilized crust was obvious, showing higher concentrations in salts and soluble nitrogen fractions than the unstabilized dune sand. The recovery of the active BSC topcrust induced an enrichment of fine particles and nitrogen at the soil surface. We conclude that an enrichment of nutrients is linked to BSC recovery.

RELICS OF TERTIARY WEATHERING IN SOILS OF THE SWABIAN ALB, CARSTIC PLATEAU

Stahr Karl^[1], Jahn Reinhold^[2], Sauer Daniela^[1], Alaily Fayez^[1], Kallis Peter^[1]

^[1]Hohenheim University ~ Institute of Soil Science and Land Evaluation ~ Stuttgart ~ Germany ^[2]Martin-Luther-Universität Halle-Wittenberg ~ Institut für Agrar- und Ernährungswissenschaften ~ Halle ~ Germany

The so called Hamocky Swabian Alb is one of the oldest land surfaces, which does occur in Southwest Germany. In the upper Jurassic period this landscape felt dry and was never subsided under water since then. However, the time sequence of influence was different, as in the early period of Cretaceous and throughout the Paleogene it seemed to be that the groundwater level was still rather high in the area of 20 to 50 m below the surface. Only in the Neogene and Pleistocene period, the plateau raised due to alpine orogenesis and following tilting of the tectonic landscapes of south Germany it rose up to 500 to 1000 m. Also the climate development has influenced the soil cover as it was till the end of Paleogene period a warm tropical climate and then it became Mediterranean and later temperate with some periglacial periods included. In places on this plateau the formation of silicatic limestone residue has continued over millions of years. However, erosion transport of soil material and addition of Pleistocene loess has modified the soil cover. Several processes, which took place in Paleogene and Neogene period have overprinted the soil cover and are still observable as relic features. This Kaolinitization/ desilification/ rubefication / clay illuviation of layer charged clays and the formation of plinthitic concretions as well as a Neogene calcrete formation.

SOIL AGGREGATION IMPROVEMENT DUE TO SOIL MANAGEMENT ON SUGARCANE

Fernandes Carolina*^[1], Truber Priscila Viviane^[1], Silva Roniram Pereira Da^[1], Marcelo Adolfo Valente^[1], Corá José Eduardo^[1]

^[1]UNESP-Sao Paulo State University ~ Soil Science ~ Jaboticabal ~ Brazil

Soil aggregation is an important soil physical quality indicator, because it can be changed by soil use and management over time. The objective of the present work was to evaluate the soil aggregation of two clayey Red Oxisol (RO1 = 700 g kg⁻¹ and RO2 = 450 g kg⁻¹), submitted to two soybean (Sb) growing seasons, having different crops (sunnhemp (Sh) and millet (Mi)) between them, during two sugarcane (Sc) growth periods interval. The experiment took place in Brazil (21°14'05" S, 48°17'09" W). The randomized block design was used with three treatments (Sc/Sb/Sh/Sb/Sc, Sc/Sb/Mi/Sb/Sc and Sc/Sb/fallow/Sb/Sc) and five replications. Soil samples were taken from 0 - 0.10, 0.10 - 0.20, 0.20 - 0.40 and 0.40 - 0.60 m depths, at four different times: before the first soybean growing season (October/2008), before the second soybean growing season (October/2009), before planting sugarcane (February/2010) and after first sugarcane harvest (June/2011). The treatments did not affect the soil aggregation (aggregates 2.0 - 1.0 mm). However, soil aggregation on June/2011 was significantly ($p < 0.01$) higher when compared to those obtained on October/2008. The results indicated that the soil management adopted increased soil aggregation over time.

STUDYING THE TEXTURE AND CEC PROPERTIES OF SOILS DEVELOPED ON KARAJ GREEN TUFF

Saberi Moghadam Esmail^[1], Heidari Ahmad^[2], Abdollahpour Mostafa^[3]

^[1]University of Tehran, College of Agriculture & Natural Resources ~ Soil Science ~ Karaj ~ Iran, Islamic Republic of

^[2]University of Tehran. assistant professor of Agriculture & Natural Resources college ~ soil science department ~ Karaj ~ Iran, Islamic Republic of ^[3]Tarbiat Modarres University ~ Agriculture university, soil science department ~ Tehran ~ Iran, Islamic Republic of

Soils formed in volcanic materials have many distinctive physical, chemical, and mineralogical properties that are rarely found in soils derived from other parent materials. The goal of this research was to examine the properties of soils developed on Karaj green tuff. Because of Mountainous, steep and Semi-arid Climate in this region, soils were in primary levels of development and classify in entisols and inceptisols orders. The results showed that clay percentage changes between 7 to 36 and CEC changes between 14 to 32.7 cmol+/kg. the CEC/clay ratio was in range 0.78 to 4.52. high contents of CEC/clay ratio shows clay content is lower than real clay content. texture analysis of volcanic soils is challenging due to poor colloidal dispersion resulting from the presence of allophan and extremely stable aggregates. Consequently, it's important to Subtilize texture interpretation of volcanic soils.

SURVEY SEMIDETAILED SOIL OF THE FARM SCHOOL ST LOUIS - FESL/UEMA

Geusa Fonseca Dourado^[1], JosÉ Raimundo Natividade Ferreira Gama^[1], Raimundo Carvalho Filho^[1], Sandra Maria Oliveira SÁ*^[1]

^[1]UNIVERSIDADE ESTADUAL DO MARANHÃO - UEMA ~ NÚCLEO GEOAMBIENTAL - NUGEO/CCA/UEMA ~ Sao Luis ~ Brazil

The semidetailed soil survey is an important tool for management and planning of land use. The main objective of the research was to identify, classify and map soils in semi detail of the Farm School St. Louis, seeking more subsidies to the activities of experimental research, planning, planning and sustainable land use. This work constitutes a soil survey on the scale 1:25,000, held in St. Louis School Farm - FESL/UEMA, located at the State University of Maranhão in St. Louis - MA, covering an area of 67.08 ha. For this purpose, we used the method of the free way in which, 7 were georeferenced points for sample collection. For the initial delimitation of physiographic units was used 1:5,000 scale aerial photographs and topographic contour lines with equal distance in meters underground. The morphological, physical and chemical profiles have identified two classes of soils in the 1st level categorical: Ultisol and Entisols, and free mapping units: PVAd, and PACd RQo. About 95% of the classes found correspond to the Ultisols and Entisols to only 4.5%. they are soils of low fertility, well drained, sandy to sand frank, with high susceptibility to erosion. The identification of these soils give greater support to the diagnosis of land use, as well as the work of research, teaching and testing throughout the academic community.

THE NATURE OF PARENT MATERIALS IN ITALIAN MOUNTAIN SOILS: A NATIONWIDE STUDY

Mileti Florindo Antonio^[1], Iamarino Michela^[1], Terribile Fabio^[1], Vingiani Simona^{*[1]}

^[1]University of Naples Federico II ~ DISSPAPA ~ Portici (NA) ~ Italy

Recent observations in Italian mountain ecosystems indicated the presence of homogeneous soils, frequently andic, on different rock substrates and in areas of high primary productivity. Despite their distribution over large areas of the Italian mountains and their importance for ecosystems, very little is known about their genesis. It is unknown if these soils developed from i) different parent materials, in similar pedo-climatic conditions, or ii) volcanic ashes of the largest plinian eruptions (Phlegrean and Aeolian like), or iii) re-distributed eolic sediments (loess) produced by the Quaternary ice ages. Then, the aim of this work was to investigate the relationship between these particular soils and their underlying bedrock, that means to understand if/how the bedrock represents the soil parent material. In the case of volcanic parent materials occurrence, the origin district was also investigated by chemical analysis of volcanic shards. To achieve this goal, 41 soil profiles in various Italian non-volcanic mountain ecosystems were described, sampled and analyzed for the main chemical and physical properties. Moreover, the particle size distribution curves (by laser) were assessed, as well as the magnetic susceptibility and the geochemistry of 38 elements (by ICP-MS). On selected soils, mineralogy (by XRD) and volcanic glass composition (by SEM-EDS) were also evaluated. Results highlighted the importance of this integrated analytical approach to i) face the complexity of the Italian mountain areas, ii) verify frequent marked differences between soil and substrate, iii) find windblown sediments in soils, iv) assess geochemical diversity bedrock-soil between north and south of Italy.

THE SPECTROHOTOMETRIC ANALYSIS OF THE SHIRVAN STEPPE (AZERBAIJAN) SOILS

Jafarov Ali*^[1]

^[1]Institute of Soil Science and Agrochemistry of Azerbaijan National Academy of Sciences (ANAS) ~ laboratory of soil physics ~ Baku ~ Azerbaijan

The object of the research was selected in the soil of the step of Shirvan (Azerbaijan), distinguishing by a diversity of the ancient and temporary deposits of the different historical period, including different conglomerations, sand, grain of sand, silt, limestone, loam, gravel and etc. The soil samples are ready for an analysis, situated in the special curette entering the complete of spectrophotometer SF-18. Thus on the basis of spectrophotometric analysis of the different types of the soil in limits of the Shirvan steppe, the influence of the component composition of this soil is established on character and form of the curve light reflecting coefficient. In this work the spectral curve reflections on a profile of soils are investigated, transfer functions of communication between data of the top and bottom horizons are made, that is allowing at remote measurements to extrapolate the distantly obtained soils properties for the horizon data on deeper horizons. The ancient and modern sediments of the various historical period including various conglomerates, sands, sandstones were objects research, or lime-stones, loams etc. The irrigated agriculture here is from time immemorial conducted, the processes of salinization, erosion and pollution are widely developed. Here are carbonate, sulfate-hydro-carbonate, chloride-hydro-carbonate and sulfate-carbonate types of salinization. The received spectrograms on a profile of the investigated soils have shown distinction not only depending on type of soils, but also within their profile. All distinctions have been compared from structures and a condition of soils and have received corresponding explanations.

TYPOLOGY AND DIRECTIONS OF EVOLUTION OF BRUNIC ARENOSOL FROM PUSZCZA BIALA

Chojnicki Józef*^[1], Grabowska Karolina^[1], Kwasowski Wojciech^[1], Kozanecka Teresa^[1]

^[1]University of Life Sciences - SGGW ~ Department of Soil Environment Sciences ~ Warsaw ~ Poland

Puszcza Biala (White Forest) is a forest complex covering an area of almost 51,000 ha between the Bug and Narew rivers (nearly 50 km to the northeast of Warsaw). Following the WRB Soil Classifications [2006], Brunic Arenosols developed from fluvioglacial sands predominate in the area. The studied soils have the following sequence of genetic horizons in the soil profile: humus, sideric, and parent rock. In the sideric horizons an insignificant increase of the free iron content in comparison to the humus horizons was noted, whereas a considerable 2 to 3-fold increase of the contents of different forms of aluminium (free, extractable by acid ammonium oxalate and sodium pyrophosphate) was observed. Part of the soil was classified as Brunic Albic Arenosol, which indicated considerable enrichment of the sideric horizons in all studied forms of aluminium (2 to 3-fold), as well as iron (near 2-fold) in comparison to the humus horizons. XRD analysis of the clay fraction indicated the occurrence of vermiculite and kaolinite in all horizons of the studied soils and illite only in the humus horizons and parent rock. In the humus horizons of both soil subtypes occur also mixed-layered minerals, whereas the presence of mixed-layered illite-vermiculite with the superiority of the illite package was determined only in Brunic Albic Arenosol. Probably the studied Brunic Arenosol will be transformed into Brunic Albic Arenosol and further into podzol soils. The podzolization process of the soils is promoted mainly by their cover by coniferous vegetation (the Quercus robur-Pinetum plant association).

UPGRADING OF FINE LEONARDITE FROM THRACE REGION

Engin Vedat Taylan^{*[3]}, Cocen Ilknur^[2]

^[1]Dokuz Eylul University ~ Minin Engineerin ~ Izmir ~ Turkey ^[2]Dokuz Eylul University ~ Minin Engineering ~ Izmir ~ Turkey ^[3]Dokuz Eylul University ~ Minin Engineering ~ Izmir ~ Turkey

Farming is the most important source of income for the people living in the Thrace region of Turkey. However, the extensive use of chemical fertilizers in farming has caused some deleterious impacts on the soil and human health today. Leonardite is commonly used as a nutrient for the soil and it is very important for the agricultural activities. For this reason, characterization and concentration of the Thrace region leonardites have a great deal of importance for Turkey's economy. This study aims to define and upgrade the headsamle. For this purpose, full chemical coal, fractional ash and humic acid analyses were applied to the headsamle. Then this sample, with 47.82% total humic acid and 47.25% free humic acid, was divided into four size fractions namely, 9.51/4.75, 4.75/2, 2/0.710, 0.710/0.355 and 0.355/0 mm. The washability characteristic of 0.355/0 mm was determined by laboratory sink-float analysis according to the standard testing procedures. Its upgrading properties was investigated using a Mozley MGS concentrator. Consequently, comparing the float sink test and MGS (Mozley) concentrator test results of the study, the most suitable concentration parameter for the subjected sample was examined.

A GUIDELINE FOR THE DEVELOPMENT OF AN INTEGRATED AND DYNAMIC MODEL OF SOIL-PLANT SYSTEM EVOLUTION

Leguédou Sophie^[1], Morel Jean-Louis^[1], Cortet Jérôme^[1], Ouvrard Stéphanie^[1], Séré Geoffroy^[1], Watteau Françoise^[1], Schwartz Christophe^[1]

^[1]INRA/Université de Lorraine ~ UMR 1120 LSE ~ Nancy ~ France

The interactions between soil and vegetation (e.g. root exudation, weathering and uptake or root growth, bioturbation and biomass production) are significant in the initial development of terrestrial ecosystems. Quantitative modelling of such interactions is needed to better understand and predict ecosystem evolution, especially in the context of derelict land restoration. However, in the current models of soil evolution, plant feedbacks on soil are still poorly taken into account. Numerous models have already been developed to reproduce individual processes involving soil and plant but they are not able to simulate the whole as a global, interactive, and complex system. Our objective is to propose a general guideline for a global dynamic model by integrating existing sub-models of individual processes. The focus is on soil under human-controlled vegetation as it is an important issue in ecosystem reclamation. The suggested guideline is based on a review of around 20 existing profile-scale quantitative sub-models which reproduce soil-plant processes. The sub-models are mainly based on a physical approach with laws of mass conservation but some rely on statistical and energy-conservation laws. At first a global soil-plant evolution model could be devised by integrating existing mass-conservation sub-models. However, adaptations are needed to reproduce interactions between processes as well as soil-plant feedbacks. Statistical and energy-based approaches could be proposed respectively for calibration and as a general metric combining various chemical or physical stresses. We assess our modelling guideline by confronting it to studies on rehabilitated ecosystems, particularly constructed Technosols as they are relevant experimental models.

ACCUMULATION OF CARBON IN POST MINING SOILS A QUANTITATIVE REVIEW

Vinduskova Olga^[1], Frouz Jan^[1]

^[1]Faculty of sciences, Charles University ~ Institute for Environmental studies ~ Prague ~ Czech Republic

In this study we performed a quantitative statistical evaluation of data from 17 studies covering 93 sites of various age reporting changes in C stock in post mining soils. Studies cover temperate sites of the Northern Hemisphere after coal mining revegetated by forest or grassland either as a consequence of reclamation or natural succession. The rate of SOC accumulation decreases with the age of sites, but follows a different trend among vegetation types. Under deciduous forest the maximum is reached after 5 to 10 years and then the rate decreases. Under coniferous forest initial values are lower but slightly increase with age reaching a maximum between 30 and 40 years. No significant trend was found under grasslands, probably because the dataset included only relatively young sites. Using only sites younger than 30 years grassland and deciduous forests seems to sequester C faster than conifers. The rate of accumulation is inversely related to temperature under coniferous forest, increased with temperature in grassland. It seems to be that conifers sequester C more in cold climate while meadows peak in warmer climate with deciduous tree being between them. Also, compared to conifers, deciduous tree species may support sequestration of SOC deeper into the soil profile which may have a positive effect on stability of this carbon stock. Topsoil application accelerates the restoration of soil organic matter content to pre-disturbance level, but it's effect can be overrated due to coal carbon present in topsoil.

Soils are the product of a complex suite of chemical, biological and physical processes. In spite of the importance of soils for society and for sustaining life on earth, our knowledge of soil formation rates and of the influence of biological activity on mineral weathering and geochemical cycles is still limited. In this contribution we will present a first synthesis of our multidisciplinary studies of the 150-year Damma glacier soil chronosequence. The aim of our research was to improve our understanding of ecosystem development on a barren substrate, of the early evolution of soils and to evaluate the influence of biological activity on weathering rates. Soil pH, cation exchange capacity, biomass, bacterial and fungal populations and soil organic matter show clear gradients related to soil age, in spite of the extreme heterogeneity of the ecosystem. The bulk mineralogy and inorganic geochemistry of the soils, in contrast, are independent of soil age and only in older soils (>100 yrs) incipient weathering is observed, mainly as a decreasing content in albite and biotite in the clay fraction by coincidental formation of secondary chlorites. Further, we document the rapid evolution of microbial- and plant-communities along the chronosequence and discuss the processes controlling carbon accumulation in these soils.

DEVELOPMENT OF SOIL CARBON POOLS AND SOIL PROPERTIES OF RESTORED BIRCH WOODLAND SITES IN SOUTHERN ICELAND

Hunziker Matthias*^[1], Nina Carle^[1], Gudmundur Halldorsson^[2], Nikolaus J. Kuhn^[1]

^[1]Physical Geography and Environmental Change ~ University of Basel ~ Basel ~ Switzerland ^[2]Research and Development ~ The Icelandic Soil Conservation Service ~ Gunnarsholt ~ Iceland

Following a period of land degradation lasting more than one thousand years, Iceland has been undertaken ambitious restoration and afforestation efforts for one century now. Yet, currently little is known on how key ecosystem factors develop effectively in afforested Icelandic woody ecosystems. In order to fill this knowledge gap the “KolBjörk” (CarbBirch), a three year (2008-2011) Icelandic ecosystem chronosequence research project, was launched. The present study which is part of “KolBjörk” aims to characterize the change of various carbon pools and associated soil properties at different old sites and their influence on soil development. Thus an eroded barren control site, five different old restored birch sites and an old native birch forest were tested in summer 2011. The soil profiles contained four sampling depth (0-5, 5-10, 10-20, 20-30 cm). In detail every depth layer per age class was represented by three samples which enclose five sub-samples each. In addition to the analysis of common pedogenetic parameters, soil organic carbon was analyzed by infrared spectroscopy. The results show that parameters changed significantly within the upper centimeters (0-5cm). In deeper horizons these observations cannot be verified for the restored sites. In comparison to old native birch forest initial ecosystems, which develop after restoration on Icelandic soils, showed a higher capability to sequester atmospheric carbon. In conclusion, it seems that restoration on degraded Icelandic soils induce specific initial ecosystems.

DROP ON STONE - A NEW TOOL FOR THE QUANTIFICATION OF BIOAVAILABLE ELEMENTS FROM WEATHERED ROCK SURFACES

Torres Natascha^{*[1]}, Gerhard Furrer^[2], Helmut Brandl^[3], Peter C. Hauser^[4], Beat Müller^[1]

^[1]Swiss Federal Institute for Environmental Science and Technology (EAWAG) ~ Surface Waters - Research and Management ~ Kastanienbaum ~ Switzerland ^[2]ETH Zurich ~ Institute of Biogeochemistry and Pollution Dynamics ~ Zurich ~ Switzerland ^[3]University of Zurich ~ Institute of Evolutionary Biology and Environmental Studies ~ Zurich ~ Switzerland ^[4]University of Basel ~ Department of Chemistry ~ Basel ~ Switzerland

The surface reactivity of rocks depends on its weathering state and controls the bioavailability of elements, which serve as nutrients for organisms and are essential for initial soil formation. Therefore, a quantitative determination of mineral-derived elements on rock surfaces is crucial. So far, most studies aiming for the quantification of weathering rates focused either on the small-scale weathering kinetics or on catchment studies of dissolved mineral components in the runoff or in soil profiles. Here we present a new method for the detection of readily available ions from granitic rock surfaces in an aqueous solution that has been spread onto those surfaces (drop on stone). The analysis is performed with a portable capillary electrophoreses (CE) instrument with capacitatively coupled contactless conductivity detection, which is suitable for analyzing very small sample volumes and suitable for on-site applications in the field. We tested the method on rock surfaces exposed along the chronosequence of a glacier forefield in the central Swiss Alps. The study was focused on the continuous increase of the granitoid rock surface's weathering state and the differences in the availability of cations and anions. Particular attention was given to the subaerial biofilms covering most rock surfaces in the sampling area. The CE measurements were complemented by the quantification of extractable adenosine triphosphate (ATP) revealing interesting relationships between the two parameters.

EXTRACELLULAR SOIL DNA: A DRIVING FORCE OF MICROBIAL LIFE IN INITIAL STAGES OF SOIL DEVELOPMENT?

Ascher Judith*^[1], Mavris Christian^[2], Garbinesi Sofia^[1], Agnelli Alberto^[3], Fornasier Flavio^[4], Lavecchia Anna^[5], Pietramellara Giacomo^[1], Egli Markus^[2]

^[1]University of Florence ~ Department of Plant, Soil and Environmental Science ~ Florence ~ Italy ^[2]University of Zurich ~ Department of Geography ~ Zürich ~ Switzerland ^[3]Università degli Studi di Perugia ~ Dipartimento di Scienze Agrarie ed Ambientali ~ Perugia ~ Italy ^[4]Consiglio per la Ricerca e la Sperimentazione in Agricoltura ~ Centro di Ricerca per lo Studio delle Relazioni tra Pianta e Suolo ~ Gorizia ~ Italy ^[5]University of Bari ~ Department of Biologia e Chimica Agroforestale ed Ambientale ~ Bari ~ Italy

Proglacial areas represent unique model-systems for monitoring soil formation processes. We correlated biotic and abiotic factors of the Morteratsch Glacier forefield (Switzerland) to characterize initial stages of soil formation (0-150 yrs). To improve the sensitivity of the assessment of primary microbial succession along the chronosequence (2 km), routine molecular analysis of soil microbial community structures and biomass based on intracellular soil DNA (iDNA) were extended to the extracellular soil DNA fraction (eDNA). Soil eDNA has to be considered a driving force of microbial life due to its features as i) quantitatively relevant portion of the soil metagenome; ii) mobile component of the soil mobilome with evolutionary implications (horizontal gene transfer via natural transformation); iii) important component of soil biofilm (physical structure; soil metagenome stability); and iv) source of microbial nutrients. Comparative sequential extraction and DGGE fingerprinting of soil eDNA and iDNA provided evidences that eDNA is a quantitative and qualitative important fraction of the soil metagenome, containing information about microbial communities that were not revealed by iDNA-fingerprinting. As the actively extruded portion of eDNA by specific bacteria along with eDNA from lysed cells constitutes the 'mobile soil mobilome', our eDNA/iDNA approach is suggested to be capable to detect rare species as well. The eDNA/iDNA ratio was further evaluated as index of microbial activity (turn-over rate of microbial biomass), in comparison to principal soil enzyme activities, and to give insight into the concept of r/K strategy in microbial primary succession as function of proceeding pedogenesis.

INFLUENCE OF SOIL HETEROGENEITY ON THE SPECIES COMPOSITION OF PLANT COMMUNITIES IN LANDS MINED FOR COAL IN SPAIN

López Marcos Daphne^[1], Turrión Nieves María Belén^[1], Martínez Ruiz Carolina^[1]

^[1]University of Valladolid ~ Agroforestry Department ~ Palencia ~ Spain

Waste-dump slopes created by mining extraction are a challenge for restoration practitioners. A clear and ecological understanding of environmental constraints is a requirement for successful revegetation. This study was conducted to evaluate the effects of the spatial variability of some physico-chemical soil parameters on plant establishment on coal-waste slopes after hydroseeding herbaceous plants. For this, a wide south-facing dump-slope with steepness of 12-35°, topsoiled and hydroseeded in October 2000 was selected for study. Two different plant communities (grassland and shrubland) were distinguished within the dump-slope and they were compared with the adjacent natural forest edge plant community. Three transects were established along the topographic gradient in each one of grassland and shrubland communities, as well as one transect in the forest community, for vegetation and soil characterization. As expected, high differences in species composition were found between forest and the other two communities, being sand content, bulk density, total nitrogen and the ratio easily oxidable carbon to total carbon the main responsible soil parameters; the two first soil parameters increasing towards the coal-mine communities, and the other two towards the forest. Differences in floristic composition between grassland and shrubland communities were due to the increase in CEC and soil deepness and the decrease in the ratio easily oxidable carbon to total carbon towards the shrubland, and it responds to an altitude-topographic gradient in which grassland community occupies the top area of the slope topographic gradient. Therefore, a good project design for dump slope reclamation should adequately consider local topoedaphic conditions.

INITIAL SOILS AND SOIL SOLUTION COMPOSITION IN AN ARTIFICIAL CATCHMENT

Schaaf Wolfgang^{*[1]}, Michael Elmer^[1], Anton Fischer^[2], Susanne Winter^[2]

^[1]BTU Cottbus ~ Soil Protection and Recultivation ~ Cottbus ~ Germany ^[2]TU München ~ Geobotany ~ Munich ~ Germany

The artificial catchment Chicken Creek was constructed 2005 in the mining area close to Cottbus/Germany to study processes of initial ecosystem development. The role of spatial and temporal structures and patterns is one of the main focus themes of the Transregional Collaborative Research Centre 38. As part of the project, initial soil characteristics and the composition of soil solution was studied over the first five years. Small differences in substrate characteristics of the initial catchment had marked effects on surface erosion, catchment hydrology and vegetation succession. Water erosion was very intensive in the first year when the unconsolidated sandy material was hardly vegetated. Soil texture influenced the form of developing erosion channels. Initial vegetation in the first year represented the soil seed bank of the substrate. In the next years, vegetation cover increased and patches started to establish first at more loamy parts within the catchments, spreading from there to the more sandy parts. Vegetation invading into the erosion channels largely reduced active erosion after three years. Soil solution composition varied considerably within the catchment at the beginning of the observation period. Compared to these spatial variations, differences in soil depth were less pronounced. Main components of all sampled soil solutions were Ca, Mg, HCO₃ and SO₄. Due to the carbonate content of the substrates, mean pH values varied between 7.0 and 8.4 in all samples. Concentrations of Ca, Mg and SO₄ decreased over the first year of measurements whereas bicarbonate concentrations increased indicating decalcification. The spatial variability decreased considerably.

In September 2009, in Hungary, several events were organized to celebrate the 100th anniversary of the 1st International Conference of Agrogeology. A symposium to overview the 100 years of advances in soil sciences and a seminar entitled "From the Dokuchaev School to Numerical Soil Classifications" were organized. As result of these discussions, a resolution (known as the "Godollo Resolution") was prepared and forwarded to the IUSS Council for discussion at the 2010 World Congress of Soil Sciences in Brisbane, Australia. The resolution stated that there is a need to develop common standards, methods and terminology in soil observations and investigations and a universal soil classification system and for a new Working Group to coordinate the efforts of this global undertaking. There was a general agreement that there is a need for evaluation of current spatial soil definition and classification systems and new innovative approaches should be investigated to develop a common universally accepted system. It was also agreed that a new working group should be set up to coordinate the work. During the 2010 World Congress of Soil Sciences in Brisbane, Australia, the IUSS Council unanimously accepted the "Godollo Resolution" and formally accepted the proposal for a new Working Group to carry out the proposed investigations and development of common standards, methods and terminology in soil observations and investigations and a universal soil classification system.

In arid environments, peculiar chemical-physical condition enhances the colonization of the mineral substrate by microorganism and plant to constitute a proto-soil (crust). The moraines are ideal sites to study primary colonization mechanism as glacier retreatment phenomena expose mineral substrate that can be colonized. Climatic and geographical conditions could differently affect the generation of proto-soil. In this work, we show the results about the characterization of proto-soil samples collected at the Nepal site (high altitude, low latitude). Seven stations were identified in the Lobuche glacier covered by black-grey biological soil crusts. The top soil fractions of each station were separated from the underlying mineral matter and both characterized. Environmental parameters (temperature, moisture, solar radiation) of the crust resulted diverse depending on the station position within the site. With regard to the deeper soil fraction, its origin seems consistent with the geological setting of the area (parent materials from granite and/or gneiss rock, slightly metamorphosed). The study of the microbiome showed different microbial communities in the crust (a-Proteobacteria class is the most abundant with the Sphingobacteriales and Rhizobiales orders) and in the deep layers. Moreover a trend of accumulation of elements in the crusts correlated with the position in the transect (highest values for lower stations) and with the depth of the crusts was found. Thus, plants and lichens within the site were classified. Multivariate analysis of both analytical data and environmental parameters will be applied to unravel the driving mechanisms involved in soil formation process.

ROLE OF CARBOXYLATES RELEASED BY MICROORGANISMS AND ROOTS OF ALPINE PIONEER PLANTS IN MOBILISING P AND METAL CATIONS DURING EARLY SOIL FORMATION

Luster Joerg^[1], Göransson Hans^[2], Brunner Ivano^[1], Frey Beat^[1], Olde Venterink Harry^[3]

^[1]Swiss Federal Research Institute WSL ~ Forest Soils and Biogeochemistry ~ Birmensdorf ~ Switzerland ^[2]Environment Centre Wales ~ - ~ Bangor ~ United Kingdom ^[3]Swiss Federal Institute of Technology ETH ~ Institute of Integrative Biology ~ Zurich ~ Switzerland

In the framework of an interdisciplinary study on initial soil formation along a deglaciation chronosequence, we examined the role of carboxylates in mobilising P and metal cations, in particular at the very early stages of soil development, where no or only little soil organic matter has built up. At selected sites with 6, 70 and 128 year old soils, soil solution was collected in-situ using micro suction cups, differentiating between the rhizosphere of specific plants and bulk soil. At the youngest site, carboxylates were enhanced in all rhizospheres exhibiting plant specific patterns, while phosphate and metal concentrations were increased in rhizospheres at all soil ages. Overall and independent of soil age, soil type and sampling date, net mobilisation of phosphate correlated strongly with the net production of tartrate, while the dissolution of metals correlated strongly with both tartrate and oxalate. A comparison with laboratory experiments on P mobilisation by plants and on granite dissolution by bacterial and fungal isolates, suggests that both bacteria and fungi are important for initial nutrient mobilisation. Bacteria, releasing mainly oxalate, are efficient in mobilising metals, while fungi, releasing mainly citrate and malate, are able to mobilise both phosphate and metals. Once first plants appear, they seem to strongly increase nutrient release from minerals in their rhizosphere with root exudation of carboxylates probably playing a two-fold role. On one hand it stimulates microbial activity, on the other hand contributes directly to weathering, in particular by means of efficient ligands such as tartrate.

THE CONTRIBUTION OF BACTERIAL CELL WALL FRAGMENTS TO THE FORMATION OF SOIL ORGANIC MATTER - A CASE STUDY FROM A GLACIER FOREFIELD

Schurig Christian^{*[1]}, Smittenberg Rienk^[2], Berger Jürgen^[3], Miltner Anja^[1], Kaestner Matthias^[1]

^[1]Helmholtz Centre for Environmental Research - UFZ ~ Environmental Biotechnology ~ Leipzig ~ Germany ^[2]ETH Zurich ~ Geology Department ~ Zurich ~ Switzerland ^[3]Max Planck Institute for Developmental Biology ~ Electron Microscopy Unit ~ Tübingen ~ Germany

Recently, stocks of soil organic matter (SOM) have been shown to decrease in European soils and also worldwide, which compromises soil fertility and enhances emissions of carbon dioxide and other, even more potent green-house gases, to the atmosphere. However, the general structure of SOM, and thereby the mechanisms behind its genesis and loss, remain unclear. In this framework, microbial biomass is generally regarded to be of low importance for SOM formation. In particular on freshly exposed sites, however, bacteria colonize barren mineral surfaces faster than fungi or higher plants. Moreover, recent results indicate that bacterial cell wall fragments frequently occur on soil mineral surfaces and also accompany the microbial colonization of previously clean and sterile activated carbon surfaces after incubation in groundwater. Hence, we hypothesized that, at least in the initial stages of soil formation, bacteria and their fragments may play an important role in particulate SOM formation bearing in mind that most dead organic matter entering the soil is processed by bacteria. This hypothesis was proven by tracing the development of SOM in a chronosequence with samples from the forefield of a receding glacier (Damma-glacier, Canton Uri, Switzerland) by scanning electron microscopy and other methods. The initially barren mineral surfaces have been shown to be rapidly covered with microbial residues as soil age increases. Moreover, this data compares well to increasing C/N-ratios, water contact angles and fatty acid contents in earlier deglaciated samples.

UNDERSTANDING THE FLUVIAL CRITICAL ZONE

Bätz Nico^{*[4]}, Stuart Lane^[4], Arnaud Temme^[6], Friederike Lang^[7]

^[1]Faculté des géosciences et de l'environnement ~ Institute of Geography, University of Lausanne ~ Lausanne ~ Switzerland ^[2]Land Dynamics Group ~ Wageningen University ~ Wageningen ~ Netherlands ^[3]Department of Soil Science, Institute of Ecology ~ Berlin University of Technology ~ Berlin ~ Germany ^[4]Institute of Geography ~ Faculté des géosciences et de l'environnement, UNIL ~ Lausanne ~ Switzerland ^[5]WUR ~ Land Dynamics Group ~ Wageningen ~ Netherlands ^[6]Land Dynamics Group ~ WUR ~ Wageningen ~ Netherlands ^[7]Department of Soil Science, Institute of Ecology ~ TUB ~ Berlin ~ Germany

Geomorphological modelling has evolved significantly the representation of the link between river morphology, flow processes and sediment transport; notably recently, with an emphasis upon the interactions between vegetation dynamics and morphodynamics. Nevertheless, vegetation dynamics have tended to be treated as a simplistic “black box” in which time replaces the more complex underlying processes. Thus, riparian vegetation dynamics not only result from interactions between surface-flow, topography and vegetation resistance to disturbance, but also soil development within the fluvial zone, which affects nutrient and water supply. More generally labeled the critical zone, there is a lack of considering the “critical fluvial zone” in geomorphological models. Understanding the key drivers of this system, thus the processes interrelating vegetation, topography, soil (formation), subsurface- and surface-flow, are crucial to understand how riverine landscapes respond to increasing human pressure and to climate change. In this poster, we consider the likely nature of a braided river critical fluvial zone. Braided rivers in deglaciated forelands provide an opportunity to study the fluvial critical zone due to their dynamic properties, the restricted physical size, the simple ecosystems and the space-for-time relation caused by glacier retreatment after the “Little Ice Age”. The poster aims to commence a discussion on the fluvial critical zone, showing first results about: a) the system understanding of a braided river set in a recently deglaciated alpine foreland; b) methodological approaches to quantify the identified interrelating key processes; c) how quantitative understanding can be integrated into fluvial geomorphological modelling.

ASSESSMENT OF THE EFFECT OF SOIL PHYSIOGRAPHY UNITS AND GEOMORPHIC STATUS ON LAND PREPARATION IN PART OF SAFASHAHR SUBBASIN (KOR BASIN IN SOUTH OF IRAN)

Zare Maryam^[1], Landi Ahmad^{*[2]}

^[2]shahid chamran university of Ahvaz ~ soil science ~ Ahvaz ~ Iran, Islamic Republic of

This study is part of Safashahr sub basin that located in north of Fars province of Iran. The objective was to investigate the effects of soil physiography units and geomorphic status on land preparation. Soils have extended on 4 type physiography units including Gravelly alluvial fan, Undulated Plateau & Upper Terrace, Slightly undulated Plateau & Upper Terrace and floodplain which classified in 3 orders, 3 suborders and 8 families. There are soil texture, relief and water limitations in alluvial fan. Since development of irrigated agriculture is affected by severe water restrictions thus these lands are suitable for dryland agriculture and gardening. Buried Argillic and Calcic horizons in Undulated Plateau and so sedimentary soils is verificate hydrological, climatic and pedogenic changes. Soils has created a suitable environment for agriculture due to the relatively large amount of clay particles and organic matter. We are faced with severe limitations of topography here, therefore changing in cropping pattern and a trend toward products with lower water requirements like Sunflower and Safflower can be effective. The role of faults in Slightly undulated Plateau as water resources is significant. Alluvial and calcareous layers create appropriate underground aquifers. However the land being in highlands has led frost garden products, therefore the gardening is not recommended. Due to diseases and low product diversity in crop rotation (Potato - Winter Wheat - Fallow), modifying cultivation pattern is advised. Because of marl deposits and coarse-textured soils in floodplain, holding potential of water is reduced, so agricultural development is not possible.

DECISION TREE MODELS TO SOIL MAPPING AND LAND SUITABLE CLASSIFICATION

Dalmolin Ricardo^[1], Ten Caten Alexandre^[1], Silva Carlos^[2], Ruiz Luis^[1]

^[1]UFMS ~ Soil Science Department ~ Santa Maria ~ Brazil ^[2]URI ~ Geography ~ Erechim ~ Brazil

Soil surveys for presenting basic information about soils and their distribution in the environment are needed to sustainable land management. Soils mapping in its traditional form is still predominant, but technological advances and new tools have emerged and contributed to the acquisition of important data to the knowledge of soils allowing the advancement of digital soil mapping (DSM). This technique allows to generating data at different spatial resolutions associated with quality indicators. The aim of this study was to propose a DSM for Erechim County (430 km² in Rio Grande do Sul State / Brazil), using specific areas for training and extrapolation of information to unmapped areas and to establish the assessment of land suitability classifications for growing erva mate (Ilex paraguariensis St. Hil). The study area was in a traditional farming of this crop. Covariates predictive factors related to relief and organisms were used in the WEKA data mining software models for the development of a Decision Tree (DT). DT was also used to establish the land suitability classifications having as covariates predictive parameters related to topography and soil parameters (DSM product). The proposed model showed an accuracy of the predicted soil map near 70% and accuracy of the suitability classification map close to 80%.

**DOES SOIL COMPOSITION CORRELATE WITH CORINE NOMENCLATURE IN WETLANDS? :
HUMIC SUBSTANCES AS FUNCTIONAL INDICATORS**

Grasset Charlotte*^[1], Rodriguez Célia^[1], Delolme Cécile^[2], Bornette Gudrun^[1]

^[1]LEHNA UMR 5023 - Laboratoire d'Ecologie des Hydrosystèmes Naturels et Anthropisés ~ EVZH Ecologie Végétale et Zones Humides ~ Villeurbanne ~ France ^[2]LEHNA UMR 5023 - Laboratoire d'Ecologie des Hydrosystèmes Naturels et Anthropisés ~ IPE Impact des Polluants sur les Ecosystèmes ~ Vaulx en Velin ~ France

Wetlands are among the most threatened ecosystems in the world, making necessary to understand their functioning and what threatens their ecological well-being. However, the word wetland gathers a huge diversity of situations, which may deeply differ in terms of functioning and conservation requirements. This work aimed at determining how far the Corine nomenclature, based on phytosociological plant units and used for classifying European wetlands, was a good tool to discriminate wetland functioning. We focused on the organic carbon quality of wetland soils, as it reflects the patterns of organic matter degradation or accumulation. 101 wetlands, representing 14 CORINE units, were sampled during summer 2010 in southeast France. The amount of Total Organic Carbon (TOC), Humic Substances (Humic Acid (HA), Fulvic Acid (FA) and Humin) and Water Extractable Organic Carbon (WEOC) were measured in the upper 20 cm of soil. TOC discriminated aquatic habitats from the others; one of the reasons is the probably higher biodegradability of aquatic plants, which have less lignified tissues. The HA/FA ratio was high for habitats with species potentially rich in refractory compounds (e.g. oligotrophic habitats, helophytes or evergreen species) and for habitats with low pH, known to inhibit the microbial activity. The proportion of HAs was higher for water meadows than for peatlands suggesting that aerated conditions would favour their accumulation. The results outlined that simple chemical descriptors may discriminate wetlands and the necessity of understanding the reasons of the contrasting patterns observed in some CORINE units: functioning heterogeneity or signals of alteration?

GLOBAL AND LOCAL PEDODIVERSITY- RESULTS FROM ARID REGIONS OF SOUTHEAST IRAN

Khademi Hossein^{*[1]}, Jafari Azam^[1], Ayoubi Shamsollah^[1]

^[1]Isfahan University of Technology ~ Soil Science ~ Isfahan ~ Iran, Islamic Republic of

A geomorphic hierarchical downscaling method was used to decompose the forms and processes forming the landscapes and their subdivisions in an arid region of southeast Iran. This paper discusses the study of pedodiversity in two ways (1) based on the global scale using the digital soil map and (2) the local pedodiversity based on geomorphic hierarchical downscaling method. The calculation of diversity indices were carried out according to taxonomic categories of order, suborder, great group, and subgroup. Using the feed forward back-propagation algorithm, a neural network was trained for prediction of the digital soil map in each category level. The results showed that the diversity indices increase from soil order to soil subgroup at global and local scales. Therefore, the greater number of soil units or higher density of the soil map, the higher diversity at the subgroup category. An increase in K-entropy of soil and landscape confirms the hypothesis of soil divergence evolution, whereby differences in initial conditions or local perturbations, and dynamic in stability appear to have produced more variable soils and landscapes in the study area. The global diversity obtained based on soil map, so diversity measures depend on the density of the soil map. Therefore, higher soil diversity was achieved with greater density of different soil units. It was observed that areas with more detailed soil mapping units exhibit the largest pedodiversity and it was concluded that the measure of pedodiversity depends amongst others on the detail of the soil survey in an area.

S02.03-P -5

PEDODIVERSITY INDICES IN THE ROMANIAN PLAIN

Gherghina Alina^{*[1]}, Marius Eftene^[2], Daniela Raducu^[2], Nicolae Florea^[1]

^[1]National Research-Development Institute for Soil Science, Agrochemistry and Environment Protection - ICPA Bucharest ~ Soil maps and land evaluation ~ Bucharest ~ Romania ^[2]National Research-Development Institute for Soil Science, Agrochemistry and Environment Protection - ICPA Bucharest ~ Soil genesis and ecopedology ~ Bucharest ~ Romania

Pedodiversity express quantitatively differences between the soils patterns distribution, and refers to the soil type, the surface occupied in territory and the mode of distribution. The concept of pedodiversity refers both to the soils formation (genetic diversity) and to the different patterns in territory (spatial diversity) and reflects the qualitative differences between the components of the soil cover (Florea, 1997, 2009). Spatial pedodiversity indicates the complexity of the soil cover, soil differences (contrast) and the pedogeographical heterogeneity, which are important features of the soil cover assemblage (Florea, 1997). The purpose of this paper is to briefly describe the indices which characterize the spatial pedodiversity in the Romanian Plain. The soil cover of the eastern part of the Romanian Plain was analyzed from morphometric point of view. Were used the following pedodiversity indices: variability, weight, topo-pedo-geographical index, size, mean area, complexity index and Shannon's diversity index. The values of these indices were calculated on the basis of soil map scale 1:200.000 and reflect the influence of pedogenetic factors in soil formation. Also, there were compared differences in pedodiversity between the Romanian Plain geographical regions and it was highlighted the impact of the agricultural practices on pedodiversity indices.

S02.03-P -6

PEDODIVERSITY OF SOIL COVER OF RUSSIAN: CARTOGRAPHIC ASSESSMENT

Alyabina Irina^{*[1]}

^[1]Moscow Lomonosov State University ~ Soil Science Faculty ~ Moscow ~ Russian Federation

In previous studies, we estimated pedodiversity of the soil cover in the European part of Russia with Shannon's diversity index, and with introduced diversity index I_d . Now we attempt to assess both a lateral spatial differentiation and a vertical differentiation of the soil cover in Russia. Attributes of the soil cover were got from the digital Soil Map of the Russian Federation (1:2.5 M). Then data were computed in delineations of the digital Map of Soil-Ecological Zoning of Russia (1:2.5 M). A vertical differentiation of the soil covers was estimated as average number of soil horizons (index of vertical differentiation – I_{vd}). A lateral spatial differentiation of the soil covers (index of lateral differentiation – I_{ld}) was calculated according to equation: $I_{ld} = n/M$ (n – a number of soil taxonomy units; M – an area falling to the share of the predominant soil). Areas of the lowest units of the soil-ecological zoning vary considerably (from tens to tens of thousands of ha). Therefore I_{ld} was reduced to a common area 1 M sq km – $I_{ld}(red)$. The calculated I_{vd} varies from 0.2 to 6.2. The calculated $I_{ld}(red)$ varies from 0.2 to 2.8. The maximum common assessment of degree of the vertical and the lateral spatial differentiation of the soil cover was found for the plain zones of Soddy-podzolic soils of southern taiga, Gray forest soils of deciduous forests, and mountain soil provinces in the Caucasus. The generated digital map makes it possible to evaluate complexity of a soil mantle that is to estimate pedodiversity.

PEDOSSEDIMENTS AND CALCRETES OF KARSTIC SINKHOLES IN QUINTANA ROO, MEXICO: A RECORD OF SOIL DEVELOPMENT, GEOMORPHIC PROCESSES AND LANDSCAPE STABILITY

Cabadas Baez Hector^[1], Solleiro Rebolledo Elizabeth^[2], Terhorst Birgit^[3], Wiesbeck Christina^[3], Sedov Sergey^[2]

^[1]POSDOCTORAL STAY UNIVERSITÄT WÜRZBURG ~ Institut für Geographie und Geologie - Physische Geographie ~ Würzburg ~ Germany ^[2]UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO ~ INSTITUTO DE GEOLOGIA-DEPARTAMENTO DE EDAFOLOGIA ~ Mexico City ~ Mexico ^[3]UNIVERSITÄT WÜRZBURG ~ Institut für Geographie und Geologie - Physische Geographie ~ Würzburg ~ Germany

The pedogenetic and geomorphic processes controlling soil development in tropical karst landscapes, are still poorly understood. We have studied thick pedosediments and calcretes in karst dissolution "pockets", developed in Late Pleistocene calcareous eolianites, in the NE coast of the Yucatan peninsula. The morphological, geochemical and mineralogical characteristics of the pockets fills, were interpreted as a record of pedogenesis and geomorphic dynamics, that shaped the soil mantle during the Holocene. Sand fraction mineralogy, Zr/Ti ratio and Rare Earth Elements (REE) pattern, indicated a mixed origin of the soil parent material; volcanic and granitic/metamorphic components, redeposited in the lithoral and coastal environments were identified. Within the soil groundmass, primary minerals were transformed by weathering and caused desilicification, accumulation of clay (hydroxy-interlayered vermiculite and kaolinite) and dithionite-citrate-bicarbonate extractable iron oxides. Reworked pedofeatures indicative of clay illuviation and redoximorphic processes were observed. This set of processes points to a continuous phase of humid pedogenesis, several thousand years long in the Early-Middle Holocene. However, the development of thick recalcified pedosediments in the pockets, contrasting with the thin background Rendzinas requires active soil redeposition, during a late phase of geomorphic activity. The radiocarbon dates indicates that the switch of the erosion/sedimentation processes could be related to ancient Maya land-use impact.

PROPERTIES AND SUSTAINABLE LEND USE OF ARENOSOLS

Sklodowski Piotr^[1], Szafranek Antoni^[2], Bielska Anna^[2]

^[1]Maria Sklodowska-Curie Warsaw Academy ~ The Faculty of Civil Engineering and Geodesy ~ Warsaw ~ Poland

^[2]Warsaw University of Technology ~ Faculty of Geodesy and Cartography, Department of Spatial Planning and Environmental Sciences ~ Warsaw ~ Poland

According to WRB classification over 29 % of soils in Poland utilized as agricultural fields are mainly Brunic Arenosols. They are mostly the very light soils formed from weakly loamy sands and loose sands. The investigated Brunic Arenosols are characterized by low water capacity, low available water to plants and very high permeability. So these soils are permanently dry. The field water capacity of Brunic Arenosols had its highest values in humus horizons and it was decreasing with the depth. Investigated sandy soils characterized by the high exchangeable and hydrolytic acidity and the high content of exchangeable aluminum. These soils characterized low sorption and buffer capacity and the low content of: organic carbon and total N. Generally productive capabilities of Brunic Arenosols are very limited. Usually they are classified to V, VI soil valuation units or to the weakly rye (6) and weakest rye (7) complex of agricultural usefulness. Arenosols classified to the weakest rye (7) complex characterized by the lowest quality and agricultural usefulness. These soils are poorest soils and ineffective from the point of view of farming and they should be generally excluded from agricultural production. Most of Brunic Arenosols of poor rye soils – complex 6 will stay significant part of the sustainable rural development and be use for crop production, however it is very important that other conditions should be considered in making decisions about their future cultivations, such as: marketability, agroecological conditions, especially ratio arable land to grassland, possibilities of land improvement.

S02.03-P -9

REFERENCE VALUES AND VARIABILITY OF SOIL PHYSICAL CHARACTERISTICS OF DELUVIAL-MEADOW SOIL

Dimitrov Emil*^[1], Kercheva Milena^[1], Shishkov Toma^[2]

^[1]Institute of Soil Science Nikola Poushkarov ~ Soil physics ~ Sofia ~ Bulgaria ^[2]Institute of Soil Science Nikola Poushkarov ~ Genesis, geography and classification ~ Sofia ~ Bulgaria

The study presents new data from two reference pits and net of boreholes (40 points) on soil physical properties of deluvial-meadow soil in the region of experimental station near Sofia. The reference pits characterized the area under grass and forest-park where cultivation has not been applied at least 40 years. The data were obtained for: soil profile morphology, soil texture, bulk density and particle density, specific soil surface, total porosity, water retention curve, content of air filled pores at different water potential, distribution of dry soil aggregates and water stable aggregates. The net sampling was realized in the surrounding areas of cultivated land covering deluvial soil and Cinnamonic forest soil (Haplic Luvisol Chromic) at the northern part. The samples from bore holes obtained at 10 cm interval (for 0-60 cm depth) and at 20 cm interval (for 60-100 cm depth) were analyzed for hygroscopic water content determined at controlled relative humidity (75%), particle size distribution, soil specific surface. In addition, the samples from 0-10 cm and 10-20 layers were analyzed for organic carbon and total nitrogen contents. These data are compared with historical data from large-scale (1:25000) survey of the area and from previous study conducted within the experimental field. The data allow to determine the reference values and natural variability of the soil physical properties and to estimate more precisely the current effects of different land use on soil physical status. Keywords: soil physical properties, soil structure, delluvial-meadow soil, Sofia region

RELIEF AS SOIL FORMING FACTOR IN KARST AREA

Bergant Janez^[4], Vrščaj Borut^[4], Repe Blaž^[2]

^[1]Agricultural institute of Slovenia ~ Department for soil and environment ~ Ljubljana ~ Slovenia ^[2]University of Ljubljana, Faculty of Arts ~ Department of Geography ~ Ljubljana ~ Slovenia ^[3]University of Ljubljana, Faculty of Arts ~ Department of Geography ~ Ljubljana ~ Slovenia ^[4]Agricultural institute of Slovenia ~ Centre for Soil and Environment Research ~ Ljubljana ~ Slovenia

Relief and parent material are the most important soil forming factors in Slovenia. This is especially true for fluvial geomorphic systems, but less for karstic geomorphic system. Karst is characterized by specific surface morphology, hydrological processes and soil morphological, physical and chemical properties. Being highly vulnerable the karst areas require detailed soil information for adequate agricultural and environment protection activities. Coarse classic vector soil maps are currently being updated with digital soil mapping techniques. This study focuses on the relationship of relief and soil genesis on karst areas in order to better incorporate the use of detailed relief information in soil inference models. Detailed field mapping and sampling was carried out along the line transects on test case area, located on limestone area of Slovenia between upper Pivka valley and Javorniki plateau. At each sampling location the measurable relief elements were registered and soil horizon morphological features were described. Soil profiles were mainly distinguished by their depth and thickness of horizons, structure, texture etc. An extreme mosaic structure in soil types and depth was found within short distances. However, a detailed analysis of sampled transects proved some relationships between relief and soil horizon incidence, thickness and other soil morphological properties. We find a lack of mikrorelief and subsurface rock morphology data, which are of great importance in karst geomorphology and pedogenesis. High resolution digital relief data are only to a certain extent relevant for soil inference modeling in karst areas and should be improved with additional spatial information.

SOILS OF GEORGIA: CONDITION AND PROBLEMS

Urushadze Teo*^[1], Urushadze Tengiz^[2]

^[1]Agrarian University of Georgia ~ Department of Agroecology ~ Tbilisi ~ Georgia ^[2]Ivane Javakhishvili Tbilisi State University ~ Department of Geography ~ Tbilisi ~ Georgia

Georgia is characterized by very interesting types of soils. Here on a very small area one can find many of the soils which are distributed in the world. It may be explained by the fact that the combinations of soil formation change on a very short distance. Professor V.V. Dokuchaev called Georgia "Museum of soils in the open air". Some of the world soils were first described in Georgia, among them Cinnamonic (Cambisols Chromic), Meadow-Cinamonic (Cambisols Chromic), Yellow-Brown Forest (Acrisols Haplic). One of the fundamental laws of soil geography – the law on vertical distribution of soils was stated on the example of the Caucasus, particularly on the example of Georgian soils. Soils of Georgia are eroded – total water eroded area – 196.7 thousand ha. Soils of Georgia are polluted by radionuclide, heavy metals, pesticides. Radionuclide contamination in Georgia took place not only during nuclear weapon tests, but also during Chernobyl atomic electric power station wreck. At that time Georgia was the fourth among the most contaminated countries after Ukraine, Belarus and Russia. The risk of pollution may be external and internal – while consuming food of vegetative and animal origin. So it may be concluded that soil cover of Georgia are characterized with big diversity. Its ecological condition is very heavy.

S02.03-P -12

THE INFLUENCE OF AIR POLLUTION ON SOIL MINERAL WEATHERING-SOIL ACIDITY IN LIMESTONE ALPS, AUSTRIA

Baatar Undrakh-Od^[1], Ottner Franz^[1], Dirnböck Thomas^[2]

^[1]Institute of Applied Geology, University of Natural Resources and Life Science ~ Department of Civil Engineering and Natural Hazards ~ Vienna ~ Austria ^[2]Environmental Agency of Austria ~ Environmental Agency of Austria ~ Vienna ~ Austria

CCE (Coordination Centre for Effects) stated that the knowledge about the interrelation between air pollution, climate change and biodiversity has already progressed. They emphasized that also atmospheric pollution in general, and nitrogen deposition in particular causes adverse effects to biodiversity. According to several studies the high input of sulphur and nitrogen leads to soil acidification in forests. The elevated input of nitrogen may have various other negative effects on natural ecosystems. In Austria the knowledge of nitrogen effects in forest is very scarce, but the studies carried out by Zechmeister et al., Environmental Agency of Austria, Huber et al., Dirnböck et al., Dirnböck & Mirtl, and Diwold et al. obtained some conclusions: Chronic nitrogen deposition has already affected soils, forest ground vegetation, epiphytic lichens and mosses. In this study several types of soils from different years (1994 and 2004) were investigated from International Cooperation Program forest level plots in Limestone Alps of Austria (National Park-Kalkalpen). Total soil mineral analyses, as well as clay mineral analysis were conducted to evaluate soil weathering processes related to air pollution effect.

VARIABILITY OF SOIL PROPERTIES WITHIN LARGE TERMITE MOUNDS – ORIGINS AND APPLICATIONS.

Erens Hans^[1], Mujinya Bazirake Basile^[1], Van Ranst Eric^[1], Boeckx Pascal^[2], Mees Florias^[3], Baert Geert^[4]

^[1]Ghent University ~ Department of Geology and Soil Science ~ Ghent ~ Belgium ^[2]Ghent University ~ Laboratory of Applied Physical Chemistry – ISOFYS ~ Ghent ~ Belgium ^[3]Royal Museum for Central Africa ~ Department of Geology and Mineralogy ~ Tervuren ~ Belgium ^[4]University College Ghent ~ Department of Plant Production ~ Ghent ~ Belgium

*The miombo woodlands of South Katanga (D.R.C.) are characterized by 3 to 5 conic termite mounds ha⁻¹ built by *Macrotermes falciger*. With an average height and diameter exceeding 5 and 18 m respectively, these are some of the largest biogenic structures in the world. Mound soil properties differ considerably from those of the surrounding Ferralsols. Most notably, mound soil exhibits a finer texture, higher CEC and exchangeable basic cation content, lower SOM content, and the build-up of carbonates. However, these soil properties were found to be far from uniform in the 250 m³ that constitute an average mound. Unlike many other mound-building termite species, the mounds of *Macrotermes falciger* are largely fossil, the result of continuous erosion and recolonization of existing mounds. The termites' nesting and foraging activity, combined with other pedological processes generates a wide range of physical, chemical, and biological conditions in different parts of the mound. Besides mapping the resulting variability of soil properties within large termite mounds, this study also contemplates its origin and possible applications.*

S02.03-P -14

ECOLOGICAL FUNCTIONS OF SOILS AT UNDERGROUND GAS STORAGE TERRITORIES

Mozharova Nadezhda*^[1], Kulachkova Svetlana^[1]

^[1]Lomonosov Moscow State University ~ Soil science faculty, gasgeochemical laboratory ~ Moscow ~ Russian Federation

Soils realizing their ecological function shield, deposit, oxidize, slow down passing methane fluxes, detain and concentrate methane on soil-geochemical barriers. The soil cover due to its heterogeneity differentiates migrating methane, demonstrating various responses at gas transport mechanisms. It is capable to create powerful biogeochemical barriers for weak diffusive methane flux, preventing or reducing emission to atmosphere. Convective methane fluxes are not assimilating by soils leading to great emission to atmosphere. As a result of natural and artificial (relocated) gas deposits operation their geochemical influence on porous structures amplifies, gas and bacterial anomalies in soils appear and extend; methane emission and consumption by soils is increasing comparison with background soils. Intensity and heterogeneity of methane fluxes from subsoil depends on natural and technogenic horizontal and vertical cracks of geological structures, closely connected with modern geodynamic processes. According to the experimental and settlement data about 5-10 % vol. of natural gas general losses of underground storage are concentrated in soils. Extension and intensity of gas anomalies strongly varies and depends on hydrothermal and technological conditions. Seasonal dynamics of functioning parameters, such as concentration of methane, its bacterial oxidation in soils, emission to the atmosphere and consumption by soils from the atmosphere and also processes of methane destruction and new solid mineral formations allowed to make representation about mass balances of pollutants in soil-atmosphere system, provide the first global calculation of methane emission, its bacterial oxidation and consumption at underground storage of natural gas.

FRACTIONAL COMPOSITION OF HEAVY METAL COMPOUNDS IN THE SOILS

Minkina Tatiana*^[1], Motusova Galina^[2], Nasarenko Olga^[3], Mandzhieva Saglara^[4], Buratchevskaya Marina^[1]

^[1]Southern Federal University ~ Soil Science ~ Rostov-on-Don ~ Russian Federation ^[2]Moscow State University ~ Soil Science ~ Moscow ~ Russian Federation ^[3]Don State Agrarian University ~ Soil Science ~ Rostov-on-Don ~ Russian Federation ^[4]Southern Federal University ~ Soil Science ~ Rostov-on-Don ~ Russian Federation ^[5]Southern Federal University ~ Soil Science ~ Rostov-on-Don ~ Russian Federation

A combined approach for fractioning metal compounds in soils on the basis of sequential and parallel extractions is proposed. On this base the effect of natural and technogenic factors on the state of Cu, Zn, Pb, Mn, Cr, Ni and Cd and the role of individual soil components in the retention of metals in soils of areas adjacent to the Novocherkassk power station has been revealed. Changes of the content of metals and the composition of their compounds in the soils of technogenic landscapes were estimated. The increasing of total content in soils of metals connected with technogenic emissions. It was marked the rise of metals mobility in the polluted soils and predominant participation of Cu, Pb, Mn, Cr and Ni organomineral complexes among their mobile species. The increasing of Zn and Cd mobility was provided predominantly by exchangeable forms and specifically sorbed by Fe–Mn (hydr)oxides. Organic substances and nonsilicate Fe minerals are the most involved in the strong fixation of heavy metals. The changing of metals compounds with different binding strengths to organic substances and Fe (hydr)oxides unare establish. The major hazard of contamination of the ecosystem is related to the increase in metal mobility. A higher metal mobility was found in soils with low buffering capacity.

PEDOTECHNIQUES STRATEGIES TO IMPROVE SOIL RESILIENCE AGAINST THE IMPACT OF IRRIGATION BY MUNICIPAL WASTEWATER: USING ZEOLITIZED TUFFS AS SOIL AMENDMENTS

Buondonno Andrea^{*[1]}, Capra Gian Franco^[2], Duras Maria Giustina^[2], Coppola Elio^[1], Grilli Eleonora^[1], Leone Antonio^[3], Vacca Sergio^[2]

^[1]Seconda Università di Napoli ~ Dipartimento di Scienze Ambientali ~ Caserta ~ Italy ^[2]Università di Sassari ~ Dipartimento di Scienze Botaniche, Ecologiche e Geologiche ~ Nuoro ~ Italy ^[3]ISAFoM ~ CNR ~ Ercolano ~ Italy

A research was started aiming at evaluating the possible use of natural zeolites as exchange conditioners to improve and make durable the soil resilience against the adverse effects of the use of anomalous wastewater, for irrigation purposes. To satisfy such aims, two zeolitized tuffs (ZTs), viz. a Neapolitan yellow tuff (NYT) and a clinoptilolite bearing tuff (ZCL), were tested as pedotechnical materials to improve soil resilience against the impact of treatment by a 'dirty' municipal wastewater (DMW). Soils were a sandy, alkaline Entisol, and a sandy-loam, sub-acidic Alfisol. Results showed that the presence of ZTs resulted in several favourable effects. EC decreased and pH was buffered. COD, total N and total P greatly decreased in the supernatant as ZTs content into the soil/zeolite models increased. Nitrate was greatly removed from solution likely via bio-chemical reaction thus preventing ground water pollution. Ammonium was selectively taken up from the DSW, making the zeolitized tuffs almost saturated by NH_4^+ , by exchanging both beneficial cations, such as K^+ and Ca^{2+} , thus improving their potential availability to plants, and undesirable cations such as Na^+ , thereby hindering the exchangeable sodium percentage (ESP) increase and concurrent soil salinization-alkalinization. The mobility of Pb, Cu and Zn dropped off to a large extent. On the whole, the results obtained highlight the possible positive role played by zeolitized tuffs in pedotechnique strategies to improve soil functionality, and should lead us to broaden the study focusing on soils and zeolitized material with different natures and properties.

SUSTAINABLE REMEDIATION OF PB, ZN AND CD CONTAMINATED SOIL

Jelusic Masa^{*[2]}, Lestan Domen^[2], Voglar David^[2], Vodnik Dominik^[2], Udovic Metka^[2], Grcman Helena^[2]

^[1]Biotechnical Faculty, University of Ljubljana ~ Centre for Soil and Environmental Science, Department of Agronomy ~ Ljubljana ~ Slovenia ^[2]Biotechnical Faculty, University of Ljubljana ~ Department of Agronomy ~ Ljubljana ~ Slovenia

Millions of hectares of agricultural land are contaminated world-wide. Remediation technologies have the potential to preserve now contaminated soil for safe production of food. Soil washing with chelants such as EDTA is an effective and potentially soil-friendly remediation option for toxic metal contaminated soil. However, soil washing cannot remove toxic metals from soil entirely, even at high chelant-to-metal ratios, and the long-term risks associated with residual metals are still largely unknown. Contaminated soil from Meža Valley (Pb 2140 mg kg⁻¹, Zn 700 mg kg⁻¹, Cd 16 mg kg⁻¹) was washed with increasing EDTA concentrations: 10, 30 and 60 mmol kg⁻¹ EDTA, removing 50, 70 and 80% of Pb, 11, 30 and 35% of Zn, 42, 48 and 62% of Cd respectively. The functioning of remediated soil as a plant substrate (*Brassica pekinensis*) was evaluated for a period of three months and compared against non-remediated soil. Fractionation with a 6-step sequential extraction, mobility, plant accessibility and oral bioavailability of Pb, Zn and Cd were determined. Soil chemical properties: toxic metal fractionation, pH, organic matter and carbon content, C:N ratio, micro nutrient concentration, cation-exchange capacity; soil physical properties: soil structure, water potential; soil biological properties: induced respiration, glukosidase, phosphatase (acid, alkaline), dehydrogenase; plant fitness, toxic metals uptake and photosynthetic activity was measured and will be presented.

Understanding the ecological status of soil ecosystems and the impact of anthropogenic contamination requires being able to correlate exposure to toxicants with impacts on biological communities. Several tools are already available to assess the ecotoxicity of substances, but there is still a need for new tools that are ecologically relevant and easy to use. We have developed a protocol based on the substrate-induced respiration of a soil community, using the MicroResp™ technique, to study a pollution-induced community tolerance approach. We have tested the technique in a long-term field experiment aiming at studying the effects of a sewage treatment plant with high Cd and Ni contents on plants and soil. The study shows that MicroResp™ can be used in PICT-bioassays to assess the toxicity of metal (Cd) toward soil microbial communities. A community-level physiological profile based on the mineralization of different carbon substrates was established for each soil sample, basal respiration and microbial biomass were estimated and qCO₂ were calculated. All these ecotoxicological and ecophysiological biomarkers suggest the metal gradient impact of sludge on soil microbial communities in terms of biomass, allocation of carbon demand for energy requirements versus growth and metal-induced tolerance. This study is, as our knowledge, the first to investigate micro-SIR in a contaminated soil system as a tool for measuring induced tolerance in a microbial community and microbial physiological traits.

^[1]Seconda Università degli Studi di Napoli ~ Dipartimento di Scienze Ambientali ~ Caserta ~ Italy ^[2]Università degli Studi di Sassari ~ Dipartimento di Scienze Botaniche, Ecologiche e Geologiche ~ Nuoro ~ Italy ^[3]Università degli Studi del Sannio ~ Dipartimento di Studi Geologici ed Ambientali ~ Benevento ~ Italy ^[4]Consiglio Nazionale delle Ricerche (CNR) ~ Istituto per I Sistemi Agricoli e Forestali del Mediterraneo (ISAFoM) ~ Napoli ~ Italy

A study was started aiming at assessing the suitability of zeolitized tuff as optimal mineral Human Transported Materials (HTMs) in pedotechnologies for quarry restoration. Different models of pedotechnosystems have been carried out by co-utilising (i) zeolitized tuff as natural K-rich zeolite-bearing rock with a huge cation exchange capacity and NH₄⁺ selectivity, (ii) commercial peat-amendment as source of exogenous organic matter, and (iii) a mixture of phosphorite and poultry as low-cost source of mineral P and organic nitrogen, respectively. The experimental pedotechnosystems were assembled as substrates for settlement and growth of pasture-grass. From the taxonomic point of view, they represent anthropogenic horizons designed “^Aup” according to the latest Keys to Soil Taxonomy, where the “caret” symbol (^) indicates just mineral or organic layers formed by Human Transported Materials (HTMs). In a previous research, data related to agronomic efficiency and organic matter evolution of such pedotechnosystems confirmed the relevant suitability and efficiency of zeolitized tuff as pedogenic substrates in quarry restoration. In the present paper our attention was focused on the estimation of present and potential phytonutritional efficiency through the assessment of both agronomic performance as well as residual fertility. In order to weight the key-components of the pedotechnosystems, and the possible interactions among them, conventional as well as special experimental indices were proposed. All investigated pedotechnosystems showed a huge crop production. The comparison among the experimental indices suggests that soil-plant relationships very well performed, especially for the less expensive pedotechnosystem, i.e. that fertilized with phosphorite and poultry manure without organic amendment.

EXPERIENCE USE OF WORLD SOIL RESOURCES (WRB) IN GEORGIA (ON EXAMPLE OF THE HUMID SUBTROPIC SOILS)

Kvrivishvili Tamari^[1], Urushadze Tengiz^[2], Matchavariani Lia^[3], Sanadze Ekaterine^[4], Ghambashidze Giorgi^[5]

^[1]Agrarian University of Georgia ~ Department of Agroecology, Division of Soil Science ~ Tbilisi ~ Georgia ^[2]Agrarian University of Georgia ~ Department of Agroecology, Division of Soil Science ~ Tbilisi ~ Georgia ^[3]Ivane Javakhishvili Tbilisi State University ~ Department of Geography ~ Tbilisi ~ Georgia ^[4]Agrarian University of Georgia ~ Department of Agroecology, Division of Soil Science ~ Tbilisi ~ Georgia ^[5]Agrarian University of Georgia ~ Department of Agroecology, Division of Ecological Agriculture and Nature Conservation ~ Tbilisi ~ Georgia

One of the most distribute classification-diagnostic system in the world are World Soil Resources (WRB) as example of soils correlation and international communication. Georgia characterized with very varied and interesting soil-cover. Introduce the data about Georgian soils in international soil information space are very important. In this direction were investigated soils of humid subtropics: Red, Yellow, Yellow-Podzolic and Yellow-Brown. Red soils are distribute in south-west part of humid subtropics and characterized by red color, deep profile and high content of clay with profile: A-AB-B1-B2-BC-C or A-AB-B-BC-C. The more or less high temperatures greatly enhance the effectiveness of leaching and the penetration of hydrogen ions in primary materials of the parent rocks. The argic, nitic, ferralic horizons are discharge clearly. Investigate red soil corresponding Nitisols of WRB. Yellow soils have wide area in West Georgia between 100-500 m above sea level and characterized by yellow color, deep profile and high content of clay with profile: A-AB-B-BC-C or A-B-BC-C. Yellow soils are characterized by the same intensive hydrolysis of weatherable minerals combined with a leaching of SiO₂ and bases and an accumulation of kaolinite and sesquioxides. Except argic, nitic, ferralic horizons in soil mark our cambic horizon. Yellow as well yellow-brown soils corresponding Acrisols of WRB. Yellow-podzolic soils are forming of the old marine terrace between 30-200 m above sea level and characterized with sharp differential profile: A-A1A2-A2-BC-C or A-A2-B-C. Soils marked by migration and accumulation processes. The main horizons are argic and albik. Yellow-podzolic soils corresponding Luvisols of WRB.

ADAPTING HUMUS FORM CLASSIFICATION TO WRB PRINCIPLES

Ulfert Graefe^[1], Rainer Baritz^[2], Gabriele Broll^[3], Eckart Kolb^[4], Gerhard Milbert^[5], Christine Wachendorf^[6]

^[1]IFAB ~ Institute for Applied Soil Biology ~ Hamburg ~ Germany ^[2]Federal Institute for Geosciences and Natural Resources ~ - ~ Hannover ~ Germany ^[3]University of Osnabrueck ~ Institute of Geography ~ Osnabrück ~ Germany ^[4]Technical University of Munich ~ Fachgebiet für Waldernährung und Wasserhaushalt ~ Freising ~ Germany ^[5]Geological Service North Rhine-Westphalia ~ - ~ Krefeld ~ Germany ^[6]University of Kassel ~ Department of Soil Biology and Plant Nutrition ~ Witzenhausen ~ Germany

The recently published European Reference Base for humus forms (ERB) aims to harmonize the classification of humus forms specifically required for transnational inventories and monitoring of soil conditions at the European scale. Although some of the proposed units still need to be confirmed in the field, the ERB marks a significant progress and lays the foundation for the further development of the classification. We suggest to adopt basic principles and rules of the WRB soil classification system for the classification of humus forms and topsoil conditions. This includes the restriction to two categorial levels consisting of main humus types (Mull, Moder, Amphi, Anmoor and others) at the first level, and a set of prefix and suffix qualifiers that are added to the name of the main humus type at the second level. The main humus types are differentiated according to the primary humus forming processes that have produced the characteristic humus profile (e.g. litter fragmentation, mixing with mineral soil). At the second level with qualifiers, the units are differentiated according to factors that have influenced the primary humus forming processes. Qualifiers may be related to the parent material of the humus form (e.g. Arenic, Siltic, Clayic, Histic), or to plant materials (Rhizic, Lignic), physical (Epilithic, Peyric), chemical (Eutric, Dystric), biological (Vermic, Mycotic) and hydrological (Hydric, Ombric, Rheic) characteristics. Furthermore, qualifiers related to diagnostic features of the A horizon facilitate to broaden the classification system to humus forms and topsoil conditions across the whole variety of soils and land uses.

**APPLICATION OF PEDROMETIC METHODS FOR CORRALTION OF NATIONAL SYSTEMS
WITH WRB**

Micheli Erika^[1], Lang Vince^{*[1]}, Fuchs Marta^[1], Waltner Istvan^[1], Dobos Endre^[2]

^[1]Szent Istvan University ~ Soil Science and Agricultural Chemisitry ~ Godollo ~ Hungary ^[2]University of Miskolc ~ Applied Geography ~ Miskolc ~ Hungary

Harmonization of soil data and correlation of national soil classes became an important and challenging issue in several international projects, European and global initiatives. The World Reference Base for Soil Resources (WRB) is the endorsed international correlation scheme for soil classification since 1998. The application of the WRB for correlation of profiles is a relatively easy task. Applications for correlation soil classes and especially map units however are very difficult, as there is very seldom a one to one match of classes. One often have to deal with partial memberships of classes or changing spatial distribution of the correlated soil types. The paper is discussing the traditional and new approaches of soil correlation. The application of the diagnostics, that are the basic elements of classification and at the same time represent continuous layers or properties in landscapes are promising in the spatial solutions, while calculations of taxonomic distances are promising in sematic solutions in the harmonization processes.

S02.04-P -4

APPLICATION OF THE WRB AND USDA SOIL TAXONOMY IN SOIL MAPPING ON THE EXAMPLE OF AN AREA TRANSFORMED BY MASS WASTING ACTIVITY IN GÓRY KAMIENNE (SUDETES, SW POLAND)

Musielok Lukasz*^[1], Kacprzak Andrzej^[1]

^[1] Jagiellonian University ~ Institute of Geography and Spatial Management ~ Kraków ~ Poland

The specificity of soil cover in the mountainous area of Góry Kamienne manifests itself in a mosaic-like structure which is a result of a diversity of soil forming process typical of mountain areas as well as a significant influence of Holocene mass wasting processes. Soil profiles of the study area were described and classified according to the criteria of the World Reference Base for Soil Resources (2006) and USDA Soil Taxonomy (1998). Consequently, it was possible to draw soil maps based on these classification systems and appropriate mapping guidelines. The investigated area was ca. 17,5 hectares and the maps were drawn at a scale of 1: 3 500. The obtained results of soil mapping were compared with a landform map of the investigated area and a detailed typological map of surface materials displaying soil morphology and properties without adhering to any classification system. The comparison reveals differences between the distinguished contours and soil associations depending on both the general structure as well as specific detailed criteria of classification systems used in the study. The analysis points out significant problems with proper depiction of the variability of soils in areas with varied topography, especially where intensive mass movements occur. The study also indicates a need to enrich the lists of qualifiers applicable for the RSGs of Umbrisols and Leptosols in the WRB, based on the properties of soils occurring in the investigated area. The study was financially supported by a MNiI grant no. N N306 312636.

^[1]Haute École Charlemagne ~ ~ Liège ~ Belgium ^[2]Catholic University of Leuven ~ Department Earth and Environmental Sciences ~ Leuven ~ Belgium ^[3]Gembloux Agro-Bio Tech, University of Liège ~ Soil Science Unit ~ Gembloux ~ Belgium ^[4]University College Kempen ~ Biosciences department ~ Geel ~ Belgium ^[5]Flemish Land Agency ~ VLM ~ Brugge ~ Belgium ^[6]Research Institute for Forest and Nature ~ INBO ~ Geraardsbergen ~ Belgium ^[7]University College Ghent ~ Department of Applied Bio-engineering Sciences, ~ Gent ~ Belgium ^[8]Ministry of the Walloon Region ~ ~ Namur ~ Belgium ^[9]Association for the Diffusion of Sciences ~ ~ Brussels ~ Belgium ^[10]Ghent University ~ Laboratory of Soil Science ~ Gent ~ Belgium

Soils in Belgium were mapped between 1947 and 1991 and published at a 1:20000 scale. These maps are used in land consolidation projects and for assessing soils' vulnerability to erosion and pollution. Integration of land-use and environmental policies within the European Union however requires a harmonization of different national soil classification systems. With the World Reference Base for Soil Resources (WRB) as common classification system within the Union, the authorities of Flanders and Wallonia commissioned a study to elaborate a methodology for converting the Belgian soil legend into WRB. The Belgian legend is based on field properties such as texture, drainage status and profile development. The WRB classification is based on diagnostic features defined by morphological, physical and chemical properties. A key and software programme have been developed to convert the Belgian units into WRB units. However, as many Belgian units could not unequivocally be translated into WRB units, additional guidelines had to be derived based on soil survey data classified according to WRB. The data show that principles of the legend shifted over time or were interpreted differently to take regional specificities into account. To overcome resulting ambiguities it is proposed to establish a database of reference soil profiles. Whereas, overall WRB is satisfactory for classifying soils at national level, the experience also shows that some WRB concepts may benefit from revisions to facilitate its correlation with national soil survey data.

HARMONISATION OF DATASETS ON SOIL DISTRIBUTION USING WRB – EXPERIENCES FROM A FRENCH-GERMAN CROSS-BOUNDARY SOIL MAP IN THE FRAMEWORK OF INSPIRE

Eberhardt Einar^[1], Sauter Joelle^[4], Pätzold Annett^[1], Boulonne Line^[3], Willer Jan^[1], Baritz Rainer^[1]

^[1]BGR - Federal Institute for Geosciences and Natural Resources ~ Spatial Information on Groundwater&Soil ~ Hannover ~ Germany ^[2]ARAA - Association pour la Relance Agronomique en Alsace ~ Soil ~ Schiltigheim / Strasbourg ~ France ^[3]INRA - French National Institute for Agricultural Research ~ ~ Orleans ~ France ^[4]ARAA - Association pour la Relance Agronomique en Alsace ~ ~ Strasbourg ~ France

Cross-boundary harmonised information on soil distribution is still a deliverable in the European Union. This has recently been addressed by the INSPIRE directive by giving rules how existing digital data on spatial distribution of soil should be formatted in order to be interoperable, i.e. exchangeable between electronic systems and connectable to spatially adjoining datasets without much effort. Harmonisation of such connecting datasets has been defined as a deliverable that has to be addressed if feasible only. One of the components of harmonisation is the use of the international soil classification World Reference Base for Soil Resources (WRB), for which a simplified structure is implemented in the INSPIRE Data Specifications Soil. Within the framework of the eContentPlus project GS Soil, we produced a French-German 1 : 250.000 draft soil map covering an area between south-western Germany (Baden-Württemberg) and the Région Alsace. The data originate from DONESOL soil database of INRA on the French side, and from the German soil database 1 : 200.000 (BÜK 200) from BGR. With this example, we evaluate the overall suitability of WRB, and the need of a minimum set of core parameters of soil profiles to correlate between the French and German map legends, and how the INSPIRE structure fits the ideas of the “Guidelines for constructing small-scale map legends using the World Reference Base for Soil Resources”. The example gives insights into capabilities and challenges of harmonisation between mapping projects with different philosophies and approaches.

**HARMONIZATION OF SWISS LEGACY SOIL DATA: THE SOIL INFORMATION SYSTEM
NABODAT**

Grob Urs^{*[1]}, Rehbein Kirsten^[1], Van Der Meer Markus^[1], Keller Armin^[1]

^[1]Research Station Agroscope Reckenholz-Tänikon ART ~ Swiss Soil Monitoring Network ~ Zürich ~ Switzerland

On the European scale efforts are being undertaken to translate national soil maps for a comprehensive common soil map for Europe. In the case of Switzerland, there is currently no common national soil dataset available, simply because the responsibility for soil mapping is at the cantonal level. While some cantons carried out soil mapping activities, other cantons did not map their soils for several reasons. During the last decades this led to a situation in Switzerland, where the data sources for soil information are very scattered and the soil data itself are not always interoperable. Therefore, we developed the Swiss National Soil Information System NABODAT to process and harmonize legacy soil data from various sources and from the cantons into one common system. Recently, the first projects to translate and process soil databases from different cantons started. This poster highlights the benefits of NABODAT in the context of harmonizing Swiss soil legacy data and summarizes our experiences in data processing.

S02.04-P -8

HOW TO COORDINATE SOIL INFORMATION ACROSS POLITICAL BOUNDARIES. A 1:200,000 APPROACH

Eckelmann Wolf^{*[1]}, Krug Dietmar^[1], Stegger Ulrich^[1]

^[1]Bundesanstalt für Geowissenschaften und Rohstoffe (BGR), Hannover, Germany

To coordinate soil information in Germany, a network of soil specialists of the respective authorities of the 16 federal state agencies and the Federal Institute for Geosciences and Natural Resources (BGR) has been formed. This network, the "Ad-hoc-AG Boden" synchronizes data sets, soil maps and methods across the 16 federal state areas. In 1990, this network started to develop a mutual basis for a common German soil map at scale 1:200,000. This map became the first German soil map under a standard, decided to be the only common cross border dataset for soil information of Germany. One of the most important steps in preparing a mapping manual for the 1:200,000 scales was the definition of a soil regions concept, which was later enlarged to the area of the European Union in close cooperation with the members of the European Soil Bureau Network (ESBN) (HARTWICH et al. 2006). This regional concept has turned out to be one of the most crucial prerequisites for the compilation of harmonized soil maps for the different regions. Now, where about 80 % of the German area is covered by printed maps, it is seems to be necessary to review the soil regions concept again, to recheck the consistency of the developed data bases, and to think about the development of an updated soil map of Germany at scale 1:1,000,000.

S02.04-P -9

NATURAL VS ANTHROPOGENIC TRACE METALS IN SOILS: INADEQUACY OF TAXONOMIES, USEFULNESS OF SOIL KNOWLEDGE

Baize Denis*^[1]

^[1]INRA ~ Science du Sol ~ Orleans ~ France

There is no question of denying the importance of soil classifications as languages of communication between scientists, as well as tools for soil cartographers wishing to class and compare soils. However, the highest categories of national or international systems are often used in an inappropriate way, for example as stratification units in the study of trace element contents in soils. Categories at the highest taxonomic level, such as the RSG of the WRB, are not relevant to this study because the linkage of a particular solum to a high level taxon is made according to different morphological or analytical criteria but never taking into account the geochemical inheritance from the parent material. For proper environmental soil management it's of vital importance to be able to distinguish between natural pedogeochemical concentrations and anthropogenically elevated levels of trace elements. Thanks to this distinction, it's possible to obtain an initial assessment of possible dangers to human health, especially through phytoavailability to cultivated plants. Trace metals of anthropogenic origin are much more reactive species than those of natural origin, even when the latter are abnormally abundant. Our presentation will stress on the major role played by the initial geochemical composition of the parent material and by the subsequent soil forming processes able to accumulate trace elements in certain soil horizons or to wash them down. It's the reason why pedology, its concepts and knowledge acquired over decades, is so useful in interpreting trace element concentrations and assessing risk. Various concrete examples will be presented.

TOWARDS A UNIVERSAL SOIL CLASSIFICATION SYSTEM

Pazos Mabel Susana^[1], Roca Núria^[2], Bech Jaume*^[2]

^[1]Universidad Nacional del Centro de la Provincia de Buenos Aires ~ Edafología Agrícola ~ Azul ~ Argentina

^[2]Universitat de Barcelona ~ Biologia Vegetal ~ Barcelona ~ Spain

Presently, two soil classification systems compete for global acceptance, Soil Taxonomy (ST) and WRB. Notwithstanding many harmonization intents, both systems are so different, particularly in their structure, that next step in order to have a unique universally accepted soil classification system is to develop a new one that fulfils this necessary condition. Among the many differences, the antinomy between open and closed system is of utmost importance. ST gives names to all soils at the subgroup level, while WRB provides lists of qualifiers to be used under certain priority for the different soil reference groups. The latter avoids many problems that arise from the tight ST scheme. The closed structure of ST conceptually means that any soil can be classified with its keys, but implicitly results in that some soils get a name that does not show their actual properties, and the eventual official actualization of the system, if achieved, takes too much time. Conversely, WRB allows the mentioning of all properties arising from a soil description, thus fully describing its properties. Whichever be the resulting Universal Soil Classification, an open low hierarchical level, equivalent to the present subgroup of ST, with precise and concise definition as present WRB qualifiers and clear rules of utilization, would be the best result.

TRANSLATING SOIL PROFILE DATA BETWEEN NATIONAL SOIL CLASSIFICATION SYSTEMS

Van Der Meer Markus^[1], Grob Urs^[1], Rehbein Kirsten^[1], Keller Armin^[1]

^[1]Research Station Agroscope Reckenholz-Tänikon ART ~ Swiss Soil Monitoring Network ~ Zurich ~ Switzerland

In the framework of the Swiss National Soil Information System NABODAT and data harmonization of soil legacy data we faced the problem of translating soil data from the French and German soil classification system into the Swiss one. Depending on the definition and keys of the soil attributes some soil features could be translated while for others additional algorithms and rules had to be applied. The technical processing and mapping of the comprehensive datasets were realized using the Feature Manipulation Engine (FME, Safe Software) that is originally designed for GIS data transformation and integration into various technical systems and propriety formats. FME transformation files were created to transform and convert the soil profile data sets between the different soil classification systems. This poster highlights the complexity of data processing in translating soil data between soil classification systems and demonstrates the benefits using the FME technique.

BIOLOGICAL SOIL CRUSTS IMPROVE PHYSICOCHEMICAL PROPERTIES OF SOIL SURFACE HORIZON

Chamizo Sonia^[1], Miralles-Mellado Isabel^[2], Rodriguez-Caballero Emilio^[1], Sole-Benet Alberto^[2], Domingo Francisco^[2], Canton Yolanda^{*[1]}

^[1]University of Almeria ~ Soil Science Department ~ Almeria ~ Spain ^[2]CSIC ~ Experimental Station of Arid Zones ~ Almeria ~ Spain

Water and nutrients are scarce resources in arid and semiarid ecosystems. In these systems, biological soil crusts (BSCs) occupy a wide extension in the interplant spaces.. BSCs perform an essential function in hydrological processes and nutrient cycling in drylands. BSCs modify soil roughness, porosity and cracking, thus affecting infiltration-runoff, evaporation, soil moisture and water availability. They fix carbon and nitrogen and increase organic matter of soils and reduce erosion by water and wind, preventing from the loss of fertility. However, the way in which BSCs affect soil properties varies depending on species abundance and crust composition. Cyanobacterial crusts represent the earliest successional stages of BSCs, whereas lichens and mosses appear during the later stages. We hypothesized that physicochemical properties of BSCs and of their underlying soils would improve with BSC development. Physicochemical properties of various types of soil crusts in different developmental stages and of the underlying soil from two semiarid areas in SE Spain were analysed. Our results showed that water content (at -33 kPa and -1500 kPa) increased in the crust and the underlying soil, with crust development, and that this effect was more significant on coarse than on fine-textured soils. Organic carbon and total nitrogen content also increased in the crust and its underlying soil with crust development. This enhancement in organic carbon and total nitrogen was especially important in the upper soil layer underneath the crust. Our results highlight the relevant role of BSCs in water availability and soil fertility in semiarid areas.

CHEMICAL AND MINERALOGICAL FORMS OF IRON AND MANGANESE AND FACTORS AFFECTING THEIR VERTICAL DISTRIBUTION IN SOME FOREST SOILS

Heidari Ahmad^{*[1]}, Mohebbi Sadegh Mohammad Javad^[1]

^[1]University of Tehran ~ Soil Science ~ Karaj ~ Iran, Islamic Republic of

Chemical forms and mineralogical composition of soil Fe and Mn compounds, their amounts and distribution in soil pedons are the results of several involved soil genesis processes. Fe-Mn concentrations occur in some contrasting microenvironmental conditions from soil matrix with different characteristics which are important in both soil genesis and classification and environmental aspects. In order to investigate abundance and distribution of Fe and Mn chemical forms, factors affecting them and comparison of Fe and Mn concentrations' characteristics with their adjacent soil matrix, five horizons containing Fe-Mn concentrations selected from four natural forest soils affected by aquic condition and located in north of Iran were studied. Total (Fet), free (Fed), amorphous (Feo) and DTPA extractable iron and two forms of Mn including total (Mnt) and DTPA extractable Mn were measured. Mineralogical characterization of the concentrations were performed using XRD, (SEM) and EDS methods. Results showed that organic matter by bonding Fe and Mn ions and causing to make their non-crystalline forms. Formation of argillic horizon also by reducing soil permeability and creation of waterlogged conditions influence different forms of Fe and Mn in the studied soils. Lepidocrocite, goetite, ferrihydrate were main iron minerals and birrensite was main manganese mineral in Fe-Mn concentrations. Distinct contradictory conditions of microzones of the Fe and Mn concentrations with their adjacent environment have caused to higher concentrations of Fed, Fet, Feo, Mnt and Feo/Fed ratio in Fe-Mn concentrations compared to the adjacent soil matrix and they affect on distribution of iron forms.

CRITICAL EXAMINATION OF THE PROCEDURES USED TO QUANTIFY THE PHYTOLITH POOL IN SOILS

Meunier Jean-Dominique^{*[1]}, Keller Catherine^[1], Guntzer Flore^[1], Braun Jean-Jacques^[2], Riotte Jean^[3], Krishnamurthy Anupama^[4]

^[1]Aix-Marseille University ~ CEREGE ~ Aix-en-Provence ~ France ^[2]Indian Institute of Science ~ Indo-French Cell for Water Sciences ~ Bangalore ~ India ^[3]Observatoire Midi Pyrénées ~ Géoscience Environnement Toulouse ~ Toulouse ~ France ^[4]French Institute ~ Laboratory of Palynology ~ Pondicherry ~ India

The soil phytolith pool plays a key role in the biogeochemical cycle of Si because it provides a source of silica that is easily soluble and bioavailable for plants. The concentration of soil phytoliths has recently been shown to be depleted in cultivated land. In the literature, two basic approaches are used to quantify the phytoliths: either a time-consuming physical extraction or a chemical extraction by alkaline solutions but its robustness has not been assessed yet. Improving the procedures for the quantification of soil phytolith is required for better evaluating the impact of human activity in the environment, from the soil development to global change. We present the preliminary results of a study comparing the physical extraction and extractions with Na₂CO₃ or Tiron. We show that the grain size as well as the plant type and the maturity of the phytoliths in the soil can affect the yield of the Na₂CO₃ extraction. Physical extraction and Na₂CO₃ give results within the same range (that is with differences < 100%) for sample concentrations of 0 to 2 wt % Si. Contrary to previous findings, we suggest that the physical extraction does not necessarily give an underestimation of phytoliths. The Tiron extraction, well suited for the quantification of phytoliths in plants gives higher Si concentrations than the two other techniques. However, we show that Tiron dissolves other silicates as well.

**EFFECT OF GUARD OF IMPLANTED FORESTS ON AMORPHOUS SILICA
BIOMINERALIZATIONS IN ENVIRONMENTS OF PRAIRIE, ARGENTINA**

Borrelli Natalia^[1], Osterrieth Margarita^{*[1]}

^[1]Instituto de Geología de Costas y del Cuaternario IMMYC ~ Universidad Nacional de Mar del Plata-CONICET ~ Mar del Plata ~ Argentina

Typical Argiudolls are the representative soils of the southeastern Pampas region, Argentina. The pristine vegetation predominant in the study area across the Quaternary were grasslands. The contribution of silicophytoliths along the Quaternary, in these soils reaches about 40% of the total mineralogical components. 50 years ago, a process of artificial forestation with the aim of creating recreation areas, generated the replacement of the natural grass vegetation by forest species (Eucalyptus sp., Pinus sp., Cupressus sp., Acacia sp.) in numerous wide zones. The aim of this work is to analyze the role of implanted forests in the guard of the biogenic amorphous silica pool in Argiudolls in the southeastern of the Pampean Plain, Argentina. In the grasses plot, phytoliths represent about 40% (A), 10% (B), 5% (C) of the total mineralogical components of the soil. In the arboreal plots, phytolith content is very representative too. In these plots, phytoliths represent about 40-60% (A), 20% (B) of the total mineralogical components of the soil. Although the arboreal species analyzed are no phytolith producers, the high phytolith content in these plots reflect the previous vegetal cover of grasses, not only by the representative quantities, but the morphologies observed. In arboreal plots relates to the greater development of the organic horizons and their protective effect in these plots with respect the grasses ones. All these factors allow the presence and preservation of an important pool of available biogenic silica in these soils, which is essential for their development and associated plant communities.

EFFECT OF VARIOUS SOURCES OF SILICON ON CADMIUM AND COPPER TOXICITIES IN DURUM WHEAT

Keller Catherine^{*[1]}, Rizwan Muhammad^[1], Sha Jing^[1], Meunier Jean-Dominique^[1]

^[1]Aix-Marseille University ~ CEREGE ~ Aix-en-Provence ~ France

*Silicon has not been considered as an essential element for higher plants, but has been proved to be beneficial for the growth and development of many plants, particularly graminaceous plants such as rice. Silicon accumulates in plants up to more than 10%, especially in monocots, and has been shown to alleviate various abiotic stresses including metal stress. We hypothesized that the form and the amount of Si amendment impact plant response to Cd stress in wheat. We designed an experiment with durum wheat (*Triticum turgidum* L.) that we grew on Cd or Cu-contaminated synthetic substrates or Cd-contaminated soil with various sources and amounts of Si. Amorphous Si supplied as diatomite increased biomass and Si content in the shoots and decreased significantly Cd and Cu content in shoots and roots when plants were exposed to either Cu or Cd, while vermiculite had less effect and quartz had no effect. We concluded that 1) Si present as amorphous Si (diatomite) was available for plant uptake and, to a less extent vermiculite could also provide Si to plant and, 2) amorphous Si could alleviate Cd and Cu stress induced by toxic amount of Cd or Cu in soils and thus increased wheat tolerance to Cd or Cu in soil.*

EFFECTS OF SOIL AQUIC CONDITION ON POTASSIUM AVAILABILITY IN SOME PADDY SOILS

Heidari Ahmad^{*[1]}, Raheb Alireza^[1]

^[1]University of Tehran ~ Soil Science ~ Karaj ~ Iran, Islamic Republic of

Aquic condition in paddy soils causes arising many problems in nutrients availability. Clay mineralogical composition in combination with soil water status plays an effective role in potassium forms as a major nutrient. Therefore, studies on different forms of potassium in soils have been a key focus in soil fertility management. Three forms of unavailable, slowly available and readily available K exist in normal soil equilibrium systems. Six (three paddy soils, two kiwi fruit and one citrus cultivated) pedons from northern Iran were studied for possible relationships between forms of soil potassium with the clay mineralogical suite and physico-chemical properties. Mineralogical analyses showed that smectite, illite and vermiculite were the most abundant clay minerals in the studied soils. Mean soluble and exchangeable potassium in paddy soils were rather low compared to soils which have recently undergone kiwifruit cultivation and their potassium fertilization. This study showed that while smectitic soils are rich in $\text{NH}_4\text{OAc-K}$, they have modest amounts of $\text{HNO}_3\text{-K}$, with moderate K release rates. On the other hand, illitic soils have only modest amounts of $\text{NH}_4\text{OAc-K}$ with high amounts of $\text{HNO}_3\text{-K}$, and high rates of K release. Non-exchangeable K plays a significant role in supplying available K, particularly in soils containing K-bearing minerals. Therefore determination of both exchangeable and HNO_3 -extractable K could give a better indication of the K potential and management for rice production in paddy soils. To improve rice production and potassium reserves in these paddy soils requires precise potassium management.

EFFECTS OF TOTAL AND ACTIVE CALCIUM CARBONATE EQUIVALENT ON THE AVAILABILITY OF SOME MICRONUTRIENTS IN SOIL

Heidari Ahmad^{*[1]}, Farahbakhsh Mohsen^[1], Moradi Zeinab^[1]

^[1]University of Tehran ~ Soil Science ~ Karaj ~ Iran, Islamic Republic of

Carbonates are among the most common soil constituents in arid and semiarid. Considering the soil productivity, in spite of their high carbonates most of calcareous soils do not show severe limitations compared to the other arid zone soils. This may cause some difficulties in interpretation of actual roles of soil carbonates. Carbonates, especially active carbonates may cause different problems including micronutrients deficiency in soils. This study investigates the effects of carbonates on the availability of some micronutrients amounts in four soil orders including: Inceptisols, Aridisols, Alfisols and Mollisols. Active calcium carbonate equivalent was measured according to ammonium oxalate method, and the available concentrations of the studied micronutrients were measured using DTPA extraction method. The results did not show any regression between the available concentrations of micronutrients with CCE content. However, strong regression coefficients were observed between them and ACCE at ACCE contents less than 2.5 %. After a sharp decrease at the range of 2.5 % ACCE, except for available Cu similar trends with limited tolerances were obtained for the relationships between ACCE and available Fe, Mn and Zn contents.

EFFECTS ON SOIL CLAY ASSEMBLAGE OF CORN PLANTS INOCULATED WITH ARBUSCULAR MYCORRHIZA FUNGI

Cozzolino Vincenza^[1], Velde Bruce^[3], Di Meo Vincenzo^[1], Adamo Paola^{*[1]}

^[1]UNIVERSITY OF NAPLES FEDERICO II ~ Dipartimento di Scienze del Suolo, della Pianta, dell'Ambiente e delle Produzioni Animali ~ PORTICI (NA) ~ Italy ^[2]Università di Napoli Federico II ~ Dipartimento di Scienze del Suolo, della Pianta, dell'Ambiente e delle Produzioni Animali ~ Portici (NA) ~ Italy ^[3]Ecole Normale Supérieure ~ Geology Laboratory ~ PARIS ~ France

Plants can extract K from exchangeable and non-exchangeable sites in the soil clay mineral structures. The latter, known as fixed K, is usually seen as an illite layer, i.e. an anhydrous K layer that forms a 1.0 nm structural layer unit as seen by X-ray diffraction. Nutrient availability can be enhanced in the root zone by arbuscular mycorrhiza fungi. In this study, the effects of non-inoculated and *Glomus intraradices* inoculated corn plant growth under different experimental conditions on soil K-bearing clay minerals were identified. The soil, a Vertic Xerofluvent, was planted in corn in a 2008-2010 randomized field experiment. Bulk and rhizosphere soil sampling was carried out from May to September 2010 from fertilized plots (N200P90K160 and N200P0K160) with and without plants. According to XRD analysis, three major K-bearing minerals were present in soil: smectite-rich mixed layer mineral, illite-rich mixed layer mineral and illite. Results at 40DAS indicate extraction of K from clay minerals by plant uptake, whereas at 130DAS much of the nutrient seems to be returned to the soil. There is an apparent difference between bulk and rhizosphere clays. The XRD patterns are not unequivocally affected by *Glomus* inoculation. There are observable changes in clay mineralogy in fallow unfertilized compared with fertilized soil. In the studied soil, the illite rich mixed-layer minerals seem to be the source of K absorbed by plants, while illite acts as sink of K released from the plant-microorganisms system at the end of the growing season and as source for the following crop.

EVALUATION RELATIONSHIP OF SOME SOIL CHARACTERISTICS WITH POTASSIUM Q/I CURVE PARAMETERS IN SOME SOIL OF GUILAN, PROVINCE (IRAN)

Vahdati Haniye^[1], Forghani Akbar^{*[2]}, Kavousi Masoud^[5]

^[1]university of guilan ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of ^[2]university of guilan ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of ^[3]university of guilan ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of ^[4]rice research institute ~ soil science , agril. college ~ Rasht ~ Iran, Islamic Republic of ^[5]rice research institute ~ soil science ~ Rasht ~ Iran, Islamic Republic of

So far, numerous criteria have been proposed for the evaluation of potassium absorption in soils and Q/I procedure is one of the best methods. In this method, Quantity and intensity relationship was evaluated. In this method, potassium availability and PBCK are determined. This method is very complex and need to better understanding of soil characteristics and very expensive. Soils samples were taken of central region Guilan province from depth of 0-25 cm. For a typical Q/I curve, soil samples were taken equilibrium with CaCl_2 constant concentration and different concentration of KCl. Results showed that a positive significantly correlation were between KL and clay content ($r=0.824^{**}$) and between KL and CEC ($r=0.734^*$). Another's positive and significant correlations were observed between PBCK and clay content ($r=0.746^{**}$) and also between PBCK and CEC ($r=0.635^*$). Using stepwise method showed PBCK is related to clay content ($\text{PBCK}=27.58+0.961\text{clay}$, $R^2=0.55$) and in the other hand amount of KL was significantly related to clay content and pH.

S02.05-P -11

INVOLVEMENT OF COMPLEMENTARY AND INTERACTIVE BACTERIAL COMMUNITIES IN THE WEATHERING PROCESSES AND CYCLING OF ELEMENTS IN HYDROMORPHIC PADDY SOILS .

Berthelin Jacques*^[1], Bongoua Jeanne^[1], Cebron Aurélie^[1], Yoro Gballou^[2], Yao-Kouame Albert^[3], Mustin Christian^[1]

^[2]CNRA ~ Gagnoa ~ Côte d'Ivoire ^[3]University Cocody ~ Département des Sciences du Sol ~ Abidjan ~ Cote d'Ivoire

^[1]Nancy-Université ~ LIMOS (Laboratoire des Interactions Microorganismes-Minéraux-Matière Organique dans les Sols) ~ Vandoeuvre-lès-Nancy ~ France

To progress in the knowledge of the weathering processes in the lowland paddy soils and the cycling of elements, characterization of soils and soil solutions and laboratory experiments have been done and were mainly focussed on the functions of bacterial communities. Results show redistribution of iron, aluminium, sulfur in the soils with seasonal releases of iron, sulfate, organic acids in the soil solutions. This suggest bacterial activities verified in experiments. Soils provide bioavailable reducible iron, biodegradable organic matter supporting iron reducing bacterial activities, reduced forms of sulfur used by sulfur oxidizing bacteria . Various bacterial communities have been determined using classical and molecular biology methods (PCR-TGGE). They have complementary metabolic pathways in the cycling of carbon, iron, sulphur, nitrogen, in different environmental conditions: fermentative facultative iron reducers (Bacillus, Clostridium...), iron respiring (Geobacillus, Alkaliphilus...), sulphur oxidizers (Thiobacilli...), sulfate reducers (Desulfovibrio...). They have also heterotrophic, autotrophic, aero anaerobic, anaerobic metabolic properties, indicating a large diversity and adaptability in their activities and play a major role in the cycling of elements and in the coupling of biogeochemical cycles.

IRON OXIDES ARE STABILISED AS DISPERSED, NANO-SIZED AGGREGATES IN SOIL EFFLUENTS

Fritzsche Andreas^{*[1]}, Schröder Christian^[2], Rennert Thilo^[3], Wieczorek Arkadiusz K.^[1], Händel Matthias^[1], Totsche Kai U.^[1]

^[1]Friedrich-Schiller-Universität ~ Institut für Geowissenschaften ~ Jena ~ Germany ^[2]Universität Bayreuth / Eberhard-Karls-Universität Tübingen ~ Angewandte Geowissenschaften ~ Tübingen ~ Germany ^[3]Technische Universität München ~ Lehrstuhl für Bodenkunde ~ Freising-Weihenstephan ~ Germany

Freshly precipitated iron oxides generally form settling macroaggregates. On the other hand, dispersed iron oxide nanoaggregates are mobile in the liquid phase and highly reactive. The occurrence of such colloidal iron oxides in soil solutions would have major impacts on the activity and reactivity of soils and the elemental cycling within soils. In this study, soil columns were filled with material from the topsoil horizons (Ah, Ap) of a gleyic Fluvisol and stagnic Luvisol, respectively. The columns were operated in duplicate under water-saturated conditions with a low ionic influent. The respiration of soil microorganisms induced anoxic conditions and consequently the accumulation of Fe(II) in the soil solution owing to the reductive dissolution of pedogenic iron oxides. The column effluent was re-aerated after its discharge resulting in the oxidation of Fe(II) and the precipitation of Fe oxides. Mössbauer spectroscopy and XRD revealed the formation of poorly ordered ferrihydrite. Its crystallisation was disturbed by (in)organic species that have associated with ferrihydrite. FTIR spectroscopy pointed to mainly polysaccharides, carboxyls, proteins and aromatics as available organic compounds. The aggregation decreased with decreasing effluent ionic strengths and higher organic carbon/Fe ratios. Dynamic light scattering revealed aggregate sizes as low as 50 nm, which was confirmed by AFM and SEM. The size of these ferrihydrite nanoaggregates remained constant for at least several weeks. Independent of actual dimensions, similar physical properties of the aggregate surfaces were detected. Concluding, this study demonstrates the reproducible, long-term stabilisation of ferrihydrite colloids in complex solutions like effluents from soil.

S02.05-P -13

MAGNETIC PROPERTIES OF ALLUVIAL SOILS POLLUTED WITH HEAVY METALS

Dlouha Sarka^[1], Petrovský Eduard^[1], Lubos Boruvka^[2], Kapicka Ales^[1]

^[1]Institute of Geophysics of the Academy of Sciences, Czech Republic ~ Dep. of Geomagnetism ~ Prague ~ Czech Republic ^[2]Czech University of Life Sciences, Prague ~ Dep. of soil science and soil protection ~ Prague ~ Czech Republic

Magnetic properties of soils, reflecting concentration and grain-size distribution of Fe-oxides, proved to be useful tool in assessing the soil properties in terms of various environmental conditions. In many cases, significant correlation with harmful substances, such as heavy metals, was reported. Our study is focused on the magnetic properties of alluvial soils from the Litavka floodplain (Czech Republic). The investigated area is heavily polluted with risk elements; the main source of pollution is a nearby Pb smelter. Vertical magnetic-susceptibility profiles were recorded in-situ using the SM400 device. The mass-specific magnetic susceptibility χ , frequency-dependent magnetic susceptibility χ_{FD} , isothermal remanence IRM, anhysteretic remanence ARM and hysteresis parameters were measured on selected samples from the layers with contrasting magnetic susceptibility. Some of the geochemical parameters were determined; pH value, organic carbon, content of risk elements, and the content of iron-hydr(oxides). Two types of magnetic variation in soil profiles were observed corresponding to identified soil types (Fluvisols, and Gleyic Fluvisols). The measurements exhibited the magnetically enhanced layers in topsoil and significant peak in the layer of fluctuating ground water. The content of Pb, Zn and Cu correlates significantly to the susceptibility. The results of the size-dependent parameters (ARM, IRM) and the ARM/ χ ratio showed the significant difference in the size of ferrimagnetic particles of individual soil layers. The magnetically enhanced topsoil layer is characterized by relatively low χ_{FD} and ARM/ χ values, reflecting the significant presence of coarse magnetite, which can be attributed to the input of anthropogenic ferrimagnetic particles from the nearby metallurgical plant.

S02.05-P -14

MAGNETIC PROPERTIES OF IRON (OXY)HYDROXIDES IN A SUB-ALPINE HUMIC CAMBISOL

Jordanova Diana*^[1], Jordanova Neli^[1]

^[1]National Institute of Geophysics, Geodesy and Geography, BAS ~ Geophysics ~ Sofia ~ Bulgaria

Humic Cambisols are widespread in the high-altitude mountainous areas in Bulgaria. The major process, determining soil properties is the accumulation of relatively big amounts of organic matter in the uppermost levels. Humic Cambisol profile from Rila mountain (2080 m a.s.l) was sampled at 2cm depth increment and detailed magnetic, physical and geochemical analyses are carried out. Magnetic characteristics discriminate clearly the uppermost organic-rich horizon by low values of anhysteretic remanence and high-field magnetic susceptibility, and lower S-ratio. Underlying humic horizon is characterized by higher magnetic susceptibility, higher remanent magnetizations (both ARM and IRM) and S-ratio close to 1. Humic horizon is distinguished by higher clay content and total iron content, as compared to the organic horizon. Magnetic mineralogy shows distinctly different results for samples from the organic and humic horizons. DCB extraction data suggest that humic horizon contains the highest amount of well-crystalline iron oxide forms. Oxalate extraction takes negligible part of Fe, thus indicating low amounts of poorly crystalline iron oxides in the whole profile. The role of organic matter for the observed variations will be discussed. Thus, magnetic properties of the studied Humic Cambisol reflect in a very sensitive manner iron speciation and distribution along the depth.

S02.05-P -15

MAGNETIC PROPERTIES OF SOILS DEVELOPED UNDER DIFFERENT ENVIRONMENTAL SETTINGS

Jordanova Neli*^[1], Jordanova Diana^[1]

^[1]National Institute of Geophysics, Geodesy and Geography, BAS ~ Geophysics ~ Sofia ~ Bulgaria

Forms of iron oxy(hydr)oxides in soils are sensitive indicators about the environmental conditions (past and present). Rock magnetic techniques give insightful information about the concentration, grain size and kind of iron-containing minerals in soils. Thus, comprehensive analysis of the influence of these different environmental factors on magnetic signature of various soil types would give additional information about their environmental state. Detailed analyses of different type soils from diverse environments include extensive magnetic measurements (magnetic susceptibility, anhysteretic (ARM) and isothermal (IRM) remanences, hysteresis parameters); determination of physical characteristics (grain size fractions, pH) and geochemical analyses (total Fe content, oxalate- and dithionite-soluble Fe). The main results can be summarized as follows. Magnetic susceptibility and IRM, which are concentration dependent characteristics, can be used as indication of soil pH in case of aerobic soils. Pedogenic magnetic enhancement in aerobic soils is due to ferrimagnetic minerals generally linked to the clay fraction. Soils formed under waterlogged conditions show systematic decrease of magnetic grain sizes (judged from ARM/X ratio) with increasing soil pH. There is a linear relationship between total Fe content and high-field magnetic susceptibility, suggesting that most of the Fe is incorporated in the paramagnetic fraction. Ratio SIRM/X can be used to deduce the relative amount of dithionite-extractable iron (Fed). Clear depth variations of different magnetic and geochemical characteristics allow precise characterization of differentiation of the soil horizons and their description.

S02.05-P -16

MAGNETIC VISCOSITY OF TROPICAL SOILS

Igel Jan*^[1], Holger Preetz^[2]

^[1]Leibniz Institute for Applied Geophysics ~ Geoelectrics and Electromagnetics ~ Hannover ~ Germany ^[2]Leibniz Institute for Applied Geophysics ~ Geoelectrics and Electromagnetics ~ Hannover ~ Germany

A total of 473 rock and soil samples from across the tropics are investigated in this study. The data show that frequency dependent susceptibility depends on the parent material as well as on the degree of weathering. Ultrabasic and basic rocks and their derivatives have higher susceptibility and absolute frequency dependence than material originating from intermediate, acid and sedimentary rocks. Within each parent material group, absolute frequency dependence increases steadily with increasing alteration from unweathered rock to topsoil. This is an effect of either residual enrichment of weathering resistant ferrimagnetic minerals including superparamagnetic (SP) grains, comminution of larger ferrimagnetic minerals or neoformation of SP minerals during soil formation. Relative frequency dependence is generally lower than 15% for the investigated samples with some few exceptions. It increases with alteration for all igneous rocks but remains at the initially high level for sediments. This means that the relative concentration of SP minerals with respect to the total magnetic fraction changes for igneous rocks while it remains constant for sediments. Soils deriving from ultrabasic, basic and intermediate rocks show low relative frequency dependence and their magnetic susceptibility is mainly caused by MD lithogenic minerals whereas soils deriving from acid rocks and sediments show the highest values and their susceptibility is mainly caused by SP minerals that are either formed during pedogenesis or residually enriched.

S02.05-P -17

MICROBIAL EFFECTS ON THE REACTIVITY AND MOBILITY OF COLLOIDAL (NANO PARTICULATE) IRON-OXIDE GEOSORBENTS.

Narvekar Sneha^{*[1]}, Totsche Kai Uwe^[1]

^[1]Friedrich Schiller University of Jena ~ Hydrogeology Section, Institute of Geosciences, Friedrich-Schiller-Universität Jena ~ Jena ~ Germany

Solubility and transport of nutrients and pollutants is affected by the presence of colloidal and (nano-) particulate organomineral compounds which act as mobile geosorbents. In soils and aquifers, pure and organic modified Fe and Mn oxy-hydroxides are of particular importance as they are progressively used for environmental cleanup. Colloidal or nanoparticulate sized mobile geosorbents are extremely reactive and exhibit unique properties with decrease in size. The mobility of the iron oxy-hydroxides is governed by various processes, e.g. flocculation/dispersion, filtration and straining, accumulation at the air-water interface, and sorptive interactions with the immobile solid surfaces. Yet, a vastly underestimated factor is the effect of microorganisms on mobility and transport by, e.g., direct attack (corrosive and/or reductive dissolution, oxidative formation or bio mineralization), or indirectly by the interactions with microbially released organic substances, components of EPS or interactions with biofilms. Direct microbial effects will effect in change of size and geometry and a new arrangement of surface sites. The objective of our study is to fundamentally understand how microbe-mediated processes and interactions effect composition, structure and properties of mobile natural geosorbents and their reactivity and mobility.

MODELING FOREST SOIL AND SEDIMENT BIOGENIC SILICA CONCENTRATIONS IN A SMALL CATCHMENT AREA IN SOUTHERN FINLAND – A BAYESIAN APPROACH

Siipola Virpi*^[1], Tallberg Petra^[1], Lehtimäki Maria^[1]

^[1]University of Helsinki ~ Department of Food and Environmental Sciences ~ Helsinki ~ Finland

This study approaches the modeling of concentrations and uncertainty related to the distribution of soil and sediment biogenic silica (BSi) concentrations by means of Bayesian statistics. BSi in forest soils consists mainly of phytolith silica from plants whereas sediment-BSi consists mainly of phytoplankton (diatom) silica. There are both types of BSi in both environments but the extent of mixing is usually not known. Bayesian modeling has been used for ecological modeling with success but so far not extensively in the field of environmental chemistry. When trying to model a quantity such as concentration of an element in soil, spatial variation can be large due to changes in soil characteristics. Equations can be used to model the concentrations and uncertainty is usually associated with some variable(s) of the equation. Many times these equations are further modified to fit the data better. As the overall distribution of an element concentration can possibly be highly peaked (kurtosis) or skewed, fitting equations to data can be difficult and some information may be lost in the process. Bayesian statistics, however, allows you to incorporate all relevant information into your model. The resulting distributions give you useful information beyond mere averages of the sampled data and allow you to make predictions concerning the problem. The hypotheses are (1) the resulting silicon distributions will show similarities in skewness and kurtosis and (2) sediment concentrations are higher and more widely distributed than forest soil concentrations because of larger mixing of BSi types in sediments.

MYCORRHIZAL FUNGI TURN RULES OF WEATHERING UPSIDE DOWN

Boy Jens*^[1], Mikutta Robert^[1], Lorenz Dennis^[1], Guggenberger Georg^[1]

^[1]Leibniz University ~ Soil Science ~ Hannover ~ Germany

*Weathering is fundamental to life on earth, transforming bedrock to soil and providing most of the nutrients required for the efficient functioning of the global carbon and oxygen cycles. In a field experiment under *Alnus*, determining mycorrhizal weathering rates of five selected rock-forming minerals contrasting in stability, we found that ectomycorrhizal fungi, already known to establish close contacts between plants and mineral surfaces, selectively weather those minerals containing elements for which the host plant is in short supply. This gives rise to a chemical weathering sequence which greatly contrasts the 'classical' weathering sequence predicted from mineral structure alone: the most stable micas and microcline showed the fastest mycorrhiza-driven weathering rates ($1.8\text{--}3.3 \times 10^{-12} \text{ mol m}^{-2} \text{ s}^{-1}$), exceeding by far those predicted on the basis of proton activity alone. Despite being chemically the most labile, augite and apatite were the least dissolved minerals during the study period (9.1×10^{-13} and $8.6 \times 10^{-14} \text{ mol m}^{-2} \text{ s}^{-1}$). This overruling of the classical weathering sequence highlights the role of plant energy supply and plant symbioses in promoting the weathering rates of specific minerals, with broad implications for biogeochemical processes associated with the formation and function of the Earth surface and atmosphere.*

PHOSPHORUS CYCLES UNDER ECTOMYCORRHIZAL AND ARBUSCULAR MYCORRHIZAL ECOSYSTEMS: SIMILAR OR DIFFERENT?

Koele Nina^{*[1]}, Dickie Ian A^[1], Blum Joel D^[2], Gleason James D^[2], Lovett Gary M^[3]

^[1]Landcare Research ~ Ecosystem Processes ~ Lincoln ~ New Zealand ^[2]University of Michigan ~ Dept. of Earth and Environmental Sciences ~ Ann Arbor ~ United States ^[3]Cary Institute of Ecosystem Studies ~ Cary Institute of Ecosystem Studies ~ Millbrook ~ United States

The ecological significance of both ectomycorrhizal fungi (EM) and arbuscular mycorrhizal fungi (AM) for forest nutrient cycles remains largely unknown, especially their respective roles in mineral weathering and decomposition of recalcitrant organic matter. We used a globally unique forest pattern of sites that have been exclusively EM or AM for the past 18,000 years to investigate phosphorus (P) budgets. Foliage, wood, organic forest floor and mineral soil at different depths were sampled in 12 pairs of EM and AM forests on schists, granites and tills on the South Island of New Zealand. Total, plant available and organic P were analysed in all samples. Preliminary results indicate that virtually all mineral P originates from apatite in the parent material, and this is the largest source of P to the soils. Furthermore mineral soil layers deeper than 10 cm under EM forest sites tend to be higher in both total P and total Fe than the AM paired sites, possibly caused by binding of P to Fe (hydr)oxides in Bs horizons. Organic matter accumulation is significantly higher in AM sites. The results obtained so far do not show a significant difference in P pools between EM and AM forest ecosystems. However soil processes such as podzolization, the formation of organo-mineral constituents and the accumulation and decomposition of organic matter are likely to be differently affected by EM or AM dominance.

SI CYCLING IN A QUARTZ-RICH, FORESTED BIOGEOSYSTEM

Höhn Axel^{*[1]}, Hubert Jochheim^[1], Jörn Breuer^[2], Michael Sommer^[1]

^[1]Leibniz-Centre for Agricultural Landscape Research (ZALF) ~ Institute for Soil Landscape Research ~ Müncheberg ~ Germany ^[2]LTZ Augustenberg ~ Referat 12 Agrarökologie ~ Karlsruhe ~ Germany

After oxygen, Silicon (Si) is the most abundant element in the earth's crust. Si plays a very important role in the global carbon cycle through (i) weathering processes on geological time scales, and, (ii) Si-fluxes in to the oceans which supply diatom growth. Leaching of silica over time leads to Si losses from soils – a pedogenic process called desilication. Only few studies are focused on the Si-cycling of terrestrial biogeosystems, especially the leaching rates of Si from soils. Leaching rates are influenced by chemical processes like silicate weathering, but also as a part of the biological cycle, via the Si uptake through plants. The input of biogenic Si into the soil is controlled by litterfall and subsequent decay of the organic material. The plant derived Si will be partially dissolved, taken up by plants again or transported with the soil solution into the vadose zone. Here we present the results of a Si budget analysis on a site in northeast Germany with sandy brown earth soils under a beech forest. During a three year observation period we investigated the Si pools in different compartments of the ecosystem, the temporal dynamics of in- and outputs and the Si-fluxes between different pools using the Biome-BGC model.

*The biological uptake and transformations of silicon (Si) affect the occurrence of different Si forms and the bioavailability of Si in soil ecosystems. These processes are also important for the transport of potentially bioavailable Si from catchment areas to the water ecosystems where Si plays an important role. The cycling of silicon by terrestrial plants has been recognized lately, but the significance of fungi is not yet investigated. In this study, the importance of fungal decomposition of plant material in the dissolution of biogenic silica (BSi) was determined by laboratory experiments. Axenic study conditions were prepared using sterile 5 l plastic containers in which 80 g of stalks of wheat (*Triticum aestivum*) were placed with 300 ml of sterile Si-free water. Containers were inoculated either with basidiomycetous *Pleurotus pulmonarius* or with ascomycetous *Trichoderma harzianum*. Fungus was not added to containers which were used as controls. The containers were irrigated by sterile Si-free water and water samples from the outlets of the containers were taken at three days intervals during the experiment. Preliminary results indicate that fungal decomposition increases the dissolution of plant BSi and that fungi accumulate small concentrations of Si. Fungi are among the most important decomposers in soil and thus the results indicate that fungi might be essential components in the biogeochemical cycling of silicon in soil.*

THE INFLUENCE OF PLANT SILICA BIOMINERALIZATIONS (SILICOPHYTOLITHS), IN THE SOIL MATRIX CONSTRUCTION, IN PAMPEAN PLAIN SOILS AFFECTED BY AGRICULTURAL PRACTICES.

Osterrieth Margarita^[1], Alvarez Fernanda^[1], Borrelli Natalia^[1], Fernandez Honaine Mariana^[1]

^[1]Instituto de Investigaciones Marinas y Costeras (IIMyC). FCEyN-UNMdP. Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET). ~ Mar del Plata ~ Argentina

In Argentina, the soils of the pampean plain are one of the most fertile of the world and they have been used for agricultural activities for more than 150 years. These human activities have modified the physical, chemical and biological properties of the soils. The aim of the study is to define and quantify the presence of silicophytoliths in soils, and in the matrix of the aggregates, in the typical Argiudolls affected by agricultural practices. The presence of silicophytoliths in the soils ranges between 3% (parental material) and more than 50% (superficial horizons). In the epipedons (A) the stock of phytolith is about 59-72x10³ Kg/ha, and the stock of Si from phytolith is 25-30x10³ Kg/ha; the contribution of amorphous silica is relevant. These values are higher in the cultivated plots due to burning activities and the presence of crop residues. The matrix of the aggregates of strong pedal, is made up in turn by microaggregates with a recurring elemental composition, mainly consisting of carbon and silicon. A higher land use leads to lower carbon content and to an increment of amorphous silica, along with calcium, iron, aluminum subordinates. The weathering of silicophytoliths is an ongoing process in these soils and contribute to the formation of amorphous silica-rich matrix of the aggregates and thus to maintain stability. Despite the intensity of tillage in cultivated soils, the negative effect would be mitigated by the high contribution of the same silicophytoliths.

THE MAGNETIC PARAMETERS OF SOILS AS INDICATORS OF THEIR DIFFERENTIATION WITH DEPTH

Jelenska Maria*^[1], Beata Górka- Kostrubiec^[1], Elzbieta Król^[1], Igor Tunyi^[2]

^[1]Institute of Geophysics. Polish Academy of Sciences ~ Earth Magnetism ~ Warsaw ~ Poland ^[2]Geophysical Institute, Slovak Academy of Sciences ~ Magnetic Laboratory ~ Bratislava ~ Slovakia

The studied soils comprise profiles from brown soil and from chernozem originated from various parent rocks: loess, granite and carbonate sediments. The aim of the study is to find the set of magnetic parameters characterizing vertical structure of soil. Magnetic susceptibility, anhysteretic remanent magnetization, dependence of magnetic susceptibility on frequency of magnetic field and hysteresis parameters has been used. Magnetite/ maghemite is present in the upper part of the profile whereas hematite contribution is significant at the bottom. Soil forming conditions influence the enhancement of X in greater extend than parent material. Formation of brown soil have resulted in greater X and XARM enhancement than formation of chernozem. Brown soil is formed in humid conditions in deciduous forest whereas chernozem is characteristic for steppe areas. Vertical differentiation of soils indicated by magnetic parameters present the opportunity for magnetic characterization of pedogenic horizons. X, XARM, Ms, Mrs, Hc, Hcr alone are not sufficient for distinguishing between sharp boundaries and transition zones of individual soil horizons. X versus XARM relationship was the best indicator of horizontal differentiation of soil. On the basis of X and XARM variability we can suggest differentiation with depth of chernozem profile not described pedologically.

ZINC MINERAL WEATHERING AS AFFECTED BY PLANT ROOTS

Houben David*^[1], Sonnet Philippe^[1]

^[1]Université catholique de Louvain ~ Earth and Life Institute ~ Louvain-la-Neuve ~ Belgium

*A continuous flow experiment was carried out to quantitatively assess the effect of Italian ryegrass (*Lolium multiflorum* Lam.) root activity on the weathering of smithsonite (ZnCO_3), a common zinc mineral. Results showed that the rate of Zn release from smithsonite to leachates was doubled in the presence of plants. The strong correlation ($r = 0.95$; $p < 0.001$) between concentrations of Zn and dissolved organic carbon (DOC) exuded by the roots in leachates suggests that organic root exudates were closely involved in the smithsonite weathering. After 14 days, the total Zn amount released by smithsonite (i.e. the sum of Zn amounts lost by leaching and taken up by plant) was multiplied by a factor 2 in the presence of plants. Although this was a laboratory study and further in situ long-term investigations are required, our results clearly highlighted that plants can enhance metal release into the environment by accelerating mineral weathering. Thus, the potential role of plants on metal phases weathering should be further considered when revegetation strategies are proposed for the reclamation of heavy metal polluted soils.*

ADSORPTIVE COMPLEX OF SALINE SOILS IN VOJVODINA, SERBIA

Vasin Jovica^{*[1]}, Belic Milivoj^[1], Nešić Ljiljana^[1], Sekulic Petar^[1], Milic Stanko^[1], Ninkov Jordana^[1], Zeremski Tijana^[1]

^[1]Institute of Field and Vegetable Crops ~ Laboratory for soil and agroecology ~ Novi Sad ~ Serbia

Sampling of soil from the pedological profiles was carried out in 25 locations whose soils had been classified as solonchaks in the soil map of Vojvodina - north part of Serbia (1971). Based on field and laboratory research the soils in these locations were reclassified in accordance with the current domestic soil classification. This paper presents the analyses of soil classified to belong to the order of halomorphic soils (soil types solonchak and solonetz). The predominant water-soluble cation is Na⁺. With the depth of the soil cation content decreased in solonchaks (which follows the fall in value and salt content with depth), and the participation of cations Ca, Mg and K are increased. Indicator of alkalization - sodium adsorption ratio (SAR) has a very high value, especially in the surface solonchaks horizons. SAR is also decreased with depth. Dominant salt in the surface solonchaks horizons is Na₂CO₃. Cation Exchange Capacity (CEC) values vary between soil types, as well as between individual horizons within the pedological profile. In all tested soils the predominant adsorbed cation is calcium. Exchangeable Sodium Percentage -ESP values of solonchak with profile structure A/E-Bt-BC and iluvic (Bt) and transition (BC) horizon of solonetz are significantly higher than the value of ESP threshold (15 %). Based on the results of analysis in this study can be concluded that the pedogenesis in solonchaks has moved on from the initial process of salinization in the process of alkalization. result is a gradual transition of solonchaks in solonetz.

BANK STABILITY ON THE RIVER ELBE TOWARDS SHIP GENERATED WAVES

Neugebauer Thomas^{*[1]}, Markgraf Wibke^[1], Von Rymon-Lipinski Franziska^[1], Fuchs Elmar^[2], Peth Stefan^[1], Horn Rainer^[1]

^[1]Institute for Plant Nutrition and Soil Science ~ CAU Kiel ~ Kiel ~ Germany ^[2]Bundesanstalt für Gewässerkunde ~ Bundesanstalt für Gewässerkunde ~ Koblenz ~ Germany

The Tideelbe is an important shipping channel between Northern Sea and Hamburg. Over the past years this shipping channel was widened and deepened to suit the draft of modern container ships. Traveling on the Elbe, these ships generate waves that may cause erosion on the banks. To investigate the stability of the bank soil samples were taken from grassland and reed bed on six parts of the Tideelbe. After predrying to -6 kPa stress strain curves and stress and time dependent changes in the pore water pressure were analyzed and the precompression stress as a function of salt concentration, soil development, and soil depth determined. The wave energy that ship generate was derived as approx. 20 hPa and was applied to the predrained (-6 kPa) soil cores (236 cm³) with cyclic loading tests (50 loading cycles). During the cyclic loading test, the matrix potential and compression of the soil cores were logged. From these data the compressibility factor (C_n) of the soil cores was calculated. The soil cores from the reed bed have a greater compressibility factor than the grassland samples. The collected data show that the younger Fluvisols near to the stream channel have a lower stability, because of a lower developmental stage.

S03.01-P -3

CARBONIFEROUS CLAYSTONES TRANSFORMATIONS DURING WEATHERING AND THEIR INFLUENCE ON APPLICATION OF THE ROCKS AS A LANDFILL COVER.

Stepniewska Zofia^[1], Stefaniak Elzbieta^[2], Pytlak Anna*^[1]

^[1]The John Paul II Catholic University of Lublin ~ Biochemistry and Environmental Chemistry ~ Lublin ~ Poland ^[2]The John Paul II Catholic University of Lublin ~ Chemistry ~ Lublin ~ Poland

Exploitation of coal in Lublin Coal Basin (LCB) in 2010 reached 5,8 mln tones and resulted in production of c.a. 2,2 mln tones of a spoil consisting of carboniferous claystones. Mineral composition of the claystones is predominantly kaolinite and illite with small amounts of quartz, sulphide minerals and plant detritus. The spoil rocks may be applied as a landfill covering. However, during weathering sulfides have the potential to form acidic leachate. Additionally in coal and sulphide-rich wastes endogenic fires may occur which have to be considered prior to application of the waste rock as a landfill capping. In the study concentrations of heavy metals (Fe, Cu, Mn, As, Pb), S and C speciation of the rocks from LCB were investigated as a function of the weathering time. Aerobic and anaerobic free-draining column tests were used to assess pH and leaching behavior of basic cations and anions from rocks stored for 0 to 10 years on a pile. Rocks weathered for up to 3 years remained neutral with low sulphate ($\approx 0,01\%$) levels and pyrite concentration not exceeding 0,8 %. Materials after 5 and 10 years of storage were sulphate-rich (up to 0,32%) and acidic (pH 4,3 and 2,7). Free-draining tests revealed that Fe, Mn, Cu, As and Pb mobility in claystones from LCB increases after 5 years of storage and is more enhanced in aerobic conditions. It was concluded that rocks from LCB may be applied as landfill sealing providing that within 10 years they will be prevented from further weathering.

COMPARING SOIL WETTING AND RUNOFF GENERATION PATTERNS AT SMALL SCALE IN CONTROL AND HYDRO-MULCHED AREAS IN A BURNT MARITIME PINE STAND IN CENTRAL PORTUGAL

Prats Alegre Sérgio^[1], Malvar Cortizo Maruxa^[1], Vieira Diana Catarina Simões*^[1], Maia Paula Alexandra Aquino^[1], Faria Sílvia Regina^[1], Vasques Ana^[1], Keizer Jan Jacob^[1]

^[1]Centre for Environmental and Marine Studies (CESAM) ~ Department of Environment and Planning, University of Aveiro, 3810-193 Aveiro (Portugal); tel.: +351 234 370 349; fax: +351 234 370 309 ~ Aveiro ~ Portugal

It is well-established that runoff production after forest fires will increase and induce soil erosion. The best solution reported until now is to protect the uncovered soil with some mulch, i.e.: straw, chopped bark, or hydromulch. However, the underlying processes were not well studied yet. The objective of this research is to analyze the changes that hydromulch can induce in runoff, soil moisture, soil water repellence and eventually soil erosion. On the framework of the FCT-founded project EROSFIRE-II, a study area in a burnt pine slope was installed in April 2009. Half of eight runoff microplots (0.28 to 0.5 m²) and half of an adjacent strip were hydromulched randomly. The monitoring methodology involved: (i) weekly runoff volume readings; (ii) monthly rainfall, runoff and soil moisture data downloads from an automatic rainfall gauge, four tipping-buckets and eight soil moisture probes inserted on the adjacent strip; (iii) monthly independent measurements of soil moisture and soil water repellence (MED-test) on control and treated strips. Fifteen months results showed a strong overall reduction of runoff and erosion (70% and 80% respectively). Besides the water storage effect of hydromulching, runoff reduction was attributed to a decrease of soil water repellency, and soil erosion followed the runoff pattern. Strong soil water repellency (MED class >5 at 2,5 cm) was observed during 4 months on the control strip, whereas only 1 month on the treated area. Lower soil water repellency levels on hydro-mulching area should be attributed to an increase of 47% of soil moisture.

EFFECT OF SOLUBLE HUMIC ACIDS ON THE UPTAKE OF HEAVY METALS BY VETIVERIA ZIZANIOIDES IN CONTAMINATED MINE SOILS

Moliner Ana*^[1], Alonso-Fernández Maria José^[1], Pérez-Esteban Javier^[2], Masaguer Alberto^[1]

^[1]ETSI Agónomos, Universidad Politécnica de Madrid ~ Soil Science ~ Madrid ~ Spain ^[2]UNED ~ Departamento de Química Orgánica y Bio-Orgánica. ~ Madrid ~ Spain

Remediation of abandoned mine sites is a real challenge. Phytoremediation, the use of plants to extract contaminants, is an attractive solution since it does not imply costly technology and only requires common agricultural practices. The only handicap is the slow growth rate and low biomass production. Metals in abandoned mine soils become more stabilized with time, being strongly bonded to soil solids. In order to increase bioavailability of metals in soils, we used humic acids extracted from leonardite. Hyperaccumulator plants usually accumulate only one or two specific elements and are thus not applicable to extract multiple elements. Researchers have suggested that a plant used for phytoremediation should be fast growing, deep-rooted, easily propagated and have a high biomass production. Vetiveria zizanioides has proven to be tolerant to high concentration of metals and has very deep roots. The objective of this research was to investigate the use of humic acids from leonardite as chelators in assisted phytoextraction, using vetiveria zizanioides as the extractante plant. Results showed that each dosis of humic acids was suited for releasing different metals from the soil matrix and making them available for plant uptake. Key words: heavy metals, humic acids, leonardite, phytoextraction.

EFFECTIVENESS OF ENCLOSURES IN RESTORATION OF DEGRADED SEMI-ARID RANGELAND IN LAKE BARINGO BASIN, KENYA

Van Ranst Eric*^[1]

^[1] Ghent University ~ Geology and Soil Science ~ Gent ~ Belgium

Land degradation, mainly been attributed to overgrazing and climatic variability and change is a major problem in the semi-arid rangelands of Sub-Saharan Africa. For over 25 years, some pastoralists in northern Kenya have been restoring degraded rangeland using enclosures in response to pasture scarcity and droughts. This study aimed to establish the effectiveness of enclosures in restoring degraded semi-arid rangeland. Botanical diversity, herbage production, infiltration rate and soil loss were used as indicators of ecological restoration. Soil hydrological properties were tested using a Kamphorst simulator inside and outside the enclosures. Plant diversity and herbage yield were determined using the line transect and quadrat method respectively. Results showed higher species diversity inside than outside the enclosures, and high community similarity between the enclosures and open grazing areas. The herbaceous standing crop was significantly higher in the enclosures than in the adjacent open grazing areas. The mean sediment yield inside the enclosures was significantly lower than in the open grazing areas. A higher water infiltration rate was recorded inside the enclosures than in the open grazing areas. The higher species diversity, herbaceous production, infiltration rate, and lower soil-loss inside the enclosures than in the open grazing areas show that the process of land degradation in the study area is reversible. This study demonstrated the enclosure system as an effective way of combating soil and vegetation degradation in the semi-arid rangeland. Enclosures could thus be used to restore degraded patches in semi-arid areas under pastoral land use.

EFFECTS OF DIRECT DRILL AND CA-AMENDMENT OVER SOME BIOLOGICAL PARAMETERS OF A DEGRADED SOIL IN WESTERN SPAIN

Leon Paloma^{*[1]}, Benito Marta^[1], Hontoria Chiquinquirá^[1], Gomez Clara^[1], Gonzalez-Fernandez Pedro^[2], Espejo Rafael^[1]

^[1] E.T.S.I. Agronomos, Universidad Politecnica de Madrid ~ Edafologia ~ Madrid ~ Spain ^[2] IFAPA, Junta de Andalucia ~ Centro de Alameda del Obispo ~ Cordoba ~ Spain

Acidic soils of Cañamero's raña formation in western Spain were cleared and then cropped in the 40's of 20th century. As a consequence, extraction of Ca through the harvest resulted in a lower Ca:Al ratio which increased the Al toxicity; also, soil tillage reduced the organic matter content. These effects led to a drastic yield reduction and the retirement of many farmers. This study has evaluated different management strategies (direct drill (DD) vs traditional tillage (TT)) and a Ca-amendment application (sugar beet foam + red gypsum (SBF+RG)) to recover soil quality in this area. The evaluation has involved the study of different enzyme activities (β -glucosidase, dehydrogenase and β -glucosaminidase) as biochemical indicators and other parameters such as pH, total organic carbon or microbial biomass carbon (MBC). After 4 years of SBF+RG application and 3 years of DD, the amendment has increased the pH and the DD management has increased soil organic matter content. β -glucosidase activity has been positively affected by DD, whereas dehydrogenase activity has increased with the amendment and β -glucosaminidase activity has concentrated around crop residues. The analysis of MBC has shown a negative effect of the amendment but a positive effect of DD (without significant differences in this case). Finally, stratification ratios indicate as well a certain recovery of the natural conditions through the mentioned practices that have been also effective to prevent soil quality losses in other Mediterranean areas.

**EFFECTS OF SOIL CLEAN - UP USING LEMON GRASS ON THE INTERACTION OF
SELECTED SOIL MINERALS WITH ORGANIC POLLUTANTS: MANAGEMENT IMPLICATIONS**

Nwaichi Eucharia^{*[1]}, Akabue Jude^[1], Onyewuife Emmanuel^[1], Oyetola Serifat^[1]

^[1]University of Port Harcourt ~ Biochemistry ~ Port Harcourt ~ Nigeria

Successful soil phytoremediation presumes that the target pollutants can be made bioavailable and that a competent flora, community of potential microbial degraders either already exists and can be stimulated or that can be introduced and established. The formation of organic – mineral interfaces in a crude oil inundated “illegal oil pipe tapping soil” was studied by monitoring the variables – texture, pH, Organic carbon, total Nitrogen, available P, Dry mass loss, PAHs concentration, and Base (Ca, Mg and K) as well as the 90d resulting clean soil. The clean – up technique employed Lemon grass and introduction of Compost and Humin amendments were undertaken for comparison. After 90d, CO₂ mineralization was significant and N cycling was strongly coupled to the C cycling. Addition of compost indicated co-metabolic degradation. Also, the concomitant activity of phytoremediation and the agronomic management practice were more effective. PAHs levels above intervention values was sequestered up to > 50%. The dissipation of the 16 USEPA-listed PAHs was largely enhanced from no significant change to 50.8±12.4% (for humin amended); 62.9±7.1% (for compost amended). The study demonstrated the critical role of Organic matter in determining the fate, mobility, and bioavailability of these priority contaminants. The results also suggest that improving the composting process with optimal organic compositions may be a feasible remediation strategy in PAH contaminated soils. Keywords: Soil interactions; Contaminated Soil; Remediation; Bioavailability; PAHs; Humin

EFFECTS OF SOIL TEXTURE AND LAND USE INTERACTIONS ON ORGANIC CARBON AMOUNTS IN SOILS IN NORTH OF IRAN

Khaledian Yones^[1], Kiani Farshad*^[1], Ebrahimi Sohaila^[1]

^[1]Gorgan university of agricultural sciences and natural resources ~ soil science ~ Gorgan ~ Iran, Islamic Republic of

Limited information exists on the linkages between soil texture and land use on C storage efficiency. Soil texture was the key to attaining elevated SOC concentrations in different land use types under different management intensities. The purpose of this study was to clarify the effects of land use change on vegetation carbon storage in Ziarat forests (a tourism village located in Golestan province in the north of Iran). For this reason, four land uses including forest, pasture, cultivated and urban were selected. Soil samples of 0 to 30 cm depth were taken and analyzed by completely randomized split-plot with two geographical aspects from north and west, and designed with five replications. The effect of soil texture on POC was examined, by analyzing the relationships of clay/OC, silt/OC and clay+silt/OC ratios with soil POC in the different land uses. Analysis of samples indicated that there were a negative correlations significant statistical (<0.0001) between labile carbon with clay/OC, silt/OC and clay+silt/OC ratios. Ziarat watershed, is a main drinking water resource of Gorgan(the capital of Golestan province), so, this study demonstrated that trend of soil degradation and mismanagement caused increasing hazard of urban floods, sediment problem and human health problems due to water pollution in main city of province.

EFFECTS OF TOPSOIL REMOVAL AS A NATURE MANAGEMENT TECHNIQUE ON SOIL FUNCTIONS

Geissen Violette^{*[1]}, Wang Shiyang^[1], Oostende Klaas^[1], Zwart Kor B.^[1], Huerta Esperanza^[2], Smit Annemieke^[1]

^[1]Wageningen University and Research Center ~ Alterra - WU-LAD ~ Wageningen ~ Netherlands ^[2]El Colegio de la Frontera Sur ~ Soil fertility ~ Villahermosa ~ Mexico

We studied the effect of topsoil removal, a nature management technique used in the Netherlands and other countries in North Europe to restore heath land vegetation. Sandy soils under original heath land vegetation were compared with sites that were transformed to farmland in 1950 and sites where after the transformation topsoil removal took place 17 and 10 years ago. All soils were sandy and acidic. Topsoil removal led to a 88-94% reduction in the C storage. Therefore, the C storage and the buffer function of the soils were drastically decreased. The N and P storage in the soils where topsoil was removed was also greatly reduced. However, the N and P storage increased in the years after the removal again probably due to areal deposition (N) and input from litter (N and P). Furthermore, even 10 and 17 years after topsoil removal no re-colonization of earthworms had occurred and microbial activity was significantly reduced. This led to increased soil density in the sites without topsoil and a typical abiotic soil structure. These changes in soil properties negatively influenced several soil functions which are relevant in nature and environmental protection, e.g. Cstorage, filtering and buffering. We therefore conclude that removal of topsoil cannot be recommended as a nature management technique due to its negative effects on soil quality.

EVALUATION OF AGGREGATES DISTRIBUTION AND OF THE MEAN WEIGHT DIAMETER OF A CONSTRUCTED SOIL, IN A COAL MINING AREA, SOUTHERN BRAZIL, CULTIVED WITH DIFFERENT SPECIES

Stumpf Lizete^[1], Pauletto Eloy Antonio^{*[1]}, Fontana Fernandes Flávia^[1], Akiyoshi Sanches Suzuki Luis Eduardo^[1], Pinto Luis Fernando Spinelli^[1], Lima Claudia Liane Rodrigues De^[1], Timm Luis Carlos^[1], Silva Tiago Stumpf Da^[1]

^[1]Federal University of Pelotas ~ Soil's Department ~ Pelotas-RS ~ Brazil

*The largest Brazilian coal mine is located in Candiota municipality, southern Brazil. The open-pit mining method, adopted in this site, promotes deep changes in the topography, vegetation hydrology of area. The extraction process involves the removal of the original soil horizons, followed by the removal of the rock strata that overlies the coal seams, which are subsequently returned to the previous pit and leveled by a bulldozer. The topsoil which was removed from the mining front is then placed on top of the overburden layers, completing the construction of the soil. The use of plants that act as soil decompactors is an important strategy for the recovery of its quality. This study aimed to analyze the influence of different cover grass in a constructed soil aggregation, in the Companhia Riograndense de Mineração coal mining site, located in the municipality of Candiota, RS. The treatments studied were: T1-Vaquero Grass (*Cynodon dactylon*), T2-Braquiaria brizanta Grass (*Brachiaria brizantha*), T3 - Tanzania Grass (*Panicum maximum*), T4-Braquiaria humidicola Grass (*Brachiaria humidicola*), T5-Hemarthria Grass (*Hemarthria altissima*), T6-Tifton Grass (*Cynodon dactylon*). A constructed soil without cover crops was used as a control. For this study undeformed soil samples were collected in July, 2008 and October, 2009, in 0.00-0.05 and 0.10-0.15m layers, in which micro-aggregates and macro-aggregates percentage and mean weight diameter were obtained. It was observed that all treatments had better results when compared with the control for both layers, especially the Brachiarias that showed the highest values of mean weight diameter and percentage of macroaggregates.*

EVALUATION OF SOIL WORKABILITY USING MICROLEIS DSS IN PISTACHIO ORCHARDS OF RAFSANJAN, IRAN

Kamali Ardavan*^[1], Esfandiarpour Boroujeni Isa^[1]

^[1]Assistant professor of soil science ~ soil science ~ Rafsanjan ~ Iran, Islamic Republic of

Optimum soil moisture content is an important factor to protect the physical soil quality during tillage practices. It also specifies the time periods suitable for tillage without soil structure destruction after rainfall or irrigation in agricultural lands. Regarding to the economic importance of pistachio, assessment of soil workability should be taken into account to reach the sustainable management of the crop. This study was conducted to estimate the proper soil moisture percentage by Aljarafe statistical model of MicroLEIS DSS program for some pistachio orchards of Rafsanjan region. To compile required soil data, 17 soil pedons were excavated, described and ninety soil samples were taken from all genetic horizons of each pedon. Physical and chemical analyses were performed on each sample based on standard soil laboratory methods. Then, the obtained laboratorial data were entered to the model to determine the workability classes for each pedon. According to the observed results, the suitable moisture content is moderate to high in studied soils. Although sufficient time is available for tillage between the two irrigation periods, tillage practices in the studied area must be done based on soil moisture contents determined in this research.

S03.01-P -13

IMPACT OF GRAZING ON SOIL CHARACTERISTICS IN THE SAVANNA OF NORTHERN SENEGAL

Guillet Cecile^{*[1]}, Drahorad Sylvie^[1], Felix-Henningsen Peter^[1], Miehe Sabine^[2]

^[1]Institute for Soil Science and Soil Conservation ~ University of Gießen ~ Gießen ~ Germany ^[2]University Marburg ~ Geography ~ Marburg ~ Germany

Land degradation in arid lands can be distinguished into climate- and human-induced processes. The assessment of these processes is widely recognized as a challenge. The effect of grazing on soil properties in the Sahel was investigated in a strongly flattened quaternary aeolian dune area in the sandy Ferlo region in northern Senegal. After a long term grazing experiment, carried out over 27 years by the German GTZ, topsoils (0 – 10 cm) of grazed and ungrazed plots at the same relief position and of three different savanna types under varying local conditions (vegetation and relief) were investigated in order to characterize particle size, pH, electrical conductivity (EC) and nutrient contents (Na, K, Mg, Ca, K, P). Results of the three savanna types reveal significant differences for grazed plots in nutrient contents and particle size distribution, especially in the fraction of coarse silt. For ungrazed plots there are weaker significant differences (e.g. in particle size distribution) between savanna types while nutrient contents show no significant differences. Comparative analysis of nutrient contents of the two extreme alternatives show higher contents of total C, N, P and cation exchange capacity in topsoils of the regeneration plots. It can be concluded that the absence of grazing results in an increase in soil nutrients in the absence of grazing or that a ongoing grazing induced a slow degradation of the communal pasture.

S03.01-P -14

INFLUENCE OF MOULDBOARD PLOUGHING AND SHALLOW TILLAGE ON SOIL PHYSICAL PROPERTIES AND CROP PERFORMANCE

Parvin Nargish*^[1], Etana Ararso^[1]

^[1]Swedish University of Agricultural Sciences ~ Department of Soil and Environment ~ Uppsala ~ Sweden

With the aim of assessing the effect of shallow tillage and mouldboard ploughing on some soil physical properties (e.g., saturated hydraulic conductivity, K_s ; bulk density, B_d ; penetrometer resistance, PR ; and water retention capacity) and the performance of spring barley, this study was conducted in spring 2011 in a long-term field experiment established for different tillage experiments in 1974. Undisturbed soil samples were taken before sowing the seeds at the depth of 15-20, 25-30 and 35-40 cm for the determination of K_s , B_d and water retention in laboratory condition. Penetrometer resistance were measured in the field after one month of sowing. Plant density was also counted after one month of sowing. Field water content in 15-20 and 25-30 cm was significantly higher for mouldboard ploughing. Water retention at 1 meter suction was also significantly higher in the treatment with mouldboard ploughing. Significantly higher K_s value was found for shallow tillage at the depth of 15-20 and 25-30 cm. Soil B_d was significantly lower for mouldboard ploughing for the first two investigating depth. Significant higher PR value was found for shallow tillage especially at the depth of 5-35 cm compare to the mouldboard ploughing but the PR was within the limit for proper root growth. Plant density and crop yield were significantly higher (154 %) in shallow tilled treatment. Relative yield was also recorded higher (104 %) in shallow tillage for last 15 years. We conclude that the yield of spring barley favoured by shallow tillage.

S03.01-P -15

INFLUENCE OF SELECTED LAND USE TYPES AND SOIL TEXTURE INTERACTIONS ON SOME SOIL PHYSICAL CHARACTERISTICS IN AN ALLUVIAL LAND

Dengiz Orhan*^[1], Saglam Mustafa^[1]

^[1]Ondokuz Mayıs University ~ Soil Science and Plant Nutrition ~ Samsun ~ Turkey

Alluvial soils, formed by rivers as accumulated sediment deposited at different times, show large variations in their physical properties over short distances. Soil physical properties that have been taken into consideration in this study showed variability as a result of dynamic interactions among natural environmental factors such as parent material, land use managements and topography. The main objective of this research was to determine impact of selected land use types and different soil textures (clay, clay loam and loam) interactions on some soil physical characteristics such as soil organic matter (SOM), bulk density (BD), water stable aggregates (WSA), and hydraulic conductivity (HC) in surface layers (0-20 cm) of an alluvial land. This study was carried out in Çetinkaya district located on Bafra Deltaic Plain. The study area covers about 1365.4 ha. The main water resource to this area is Kizilirmak River. Most of the study area is flat and slightly sloped (0.0-2.0%) and the majority of research area's soils are Entisol, Inceptisol and Vertisol. The study area has been commonly used for irrigated agriculture activities particularly, for field crops (wheat, maize and barley) and for vegetables (bean, pepper, watermelon, cucumber, tomato, cabbage and spinach). According to the results of MANOVA statistical analysis, affecting different land uses was significantly found that was occurred as $p < 0.01$ for SOM, WSA, and HC, $p < 0.05$ for BD as well. In addition, while affecting of texture was significantly detected as $p < 0.01$ for SOM and WSA, it was determined statistically as $p < 0.05$ for HC.

LAND TAKE IMPACT ON SOIL RESOURCES IN TURKEY

Yigini Yusuf^[1], Gardi Ciro^[1], Montanarella Luca^[1], Tóth Gergely^[1]

^[1]European Commission Joint Research Centre ~ Institute for Environment and Sustainability ~ Ispra (VA) ~ Italy

Land take, related to urbanisation process, is one of the most significant drivers of global environmental change today. In Europe, between 2000 and 2006 more than 670,000 ha (yearly mean 113000 ha) of lands have been changed into artificial areas. In many cases the land take occurs on most fertile and valuable soils for agricultural production. That being the case, the land take process also significantly affects soil resources in Turkey. Referring the years 2000-2006, about 43000 ha of lands have been taken as a consequence of urbanisation in Turkey. This study aims to determine to what extent land take is impacting on soil resources in Turkey. For this purpose, CORINE Land Cover changes between 2000 and 2006 and land use capability data, from National Soil Information System of Turkey, were used as input data. As a result, the impacts of land take on soil resources were analysed and land take extent on each land use capability class have been calculated at country scale.

S03.01-P -17

LAND TAKE IMPACT ON SOIL RESOURCES: A METHODOLOGICAL APPROACH

Gardi Ciro^[1], Yigini Yusuf^[1], Toth Gergely^[1], Panagos Panos^[1]

^[1]Joint Resaerch Center ~ Institute for the Environment and Sustainability ~ Ispra VA ~ Italy

European Union has one of the highest population densities in the world, and a very dynamic and diverse economy. Approximately 75 % of the European population live in urban areas, and by 2020 this percentage will reach 80 %; Artificial areas, sensu Corine Land Cover, covers in Europe the equivalent of one of its medium-size state: in 10 years (1990 – 2000), Germany, Spain and France lost between 200,000 and 150,000 ha each, while in relative terms, the Netherlands are most affected as they lost 2.5 % of their agricultural land resources. In this dynamic and competitive context it is clear that the competition for the use of land, among different economic sectors, is extremely high. In this competition the agricultural sectors is often the looser. In many cases the land taken is characterized by the most fertile and valuable soils for agricultural production. This process, generally known as “land take”, can have a strong influence on food security at European level. The objective of this research is to realize a detailed assessment on the impact of Land Take on soil resources in the different member states, using the concept of Soil Quality as measure of the impact.

S03.01-P -18

LOAD INDUCED SOIL DEFORMATION UNDER CONSERVATION AND CONVENTIONAL
TILLAGE IN SOUTH NORWEGIAN SOILS

Zink Alexander*^[1]

^[1]Institute of plant nutrition and soils science ~ CAU ~ Kiel ~ Germany

Economisation and productivity enforcement in modern agriculture is still leading to higher levels of mechanisation. Combined field operations and bigger working width the requirement of higher pulling forces leads to heavier machinery during tillage. Beside tillage, machinery weight is also increasing by fertilization operations, which also cause high wheel loads on the fields. With increasing size and weight of agricultural machinery we find arable soils more and more “under pressure”. Soil compaction as a result of mechanical stress below the wheels constitutes a severe problem for sustainable agriculture. Within a cooperative project of the institute of plant nutrition and soil science of the University of Kiel and Bioforsk Institute for Agricultural and Environmental Research, Øst Apelsvoll, Norway, there were done outdoor wheeling experiments with tractors and slurry trailers up to total load of 20 Mg. Stress impact and its distribution below the wheel as well as the deformation were determined by using a combined stress state transducer (SST) and displacement transducer system (DTS). Experimental plots have been sampled in the range of the load tracks to characterize changes in soil stability parameters (precompression stress), hydraulic and aeration properties under laboratory conditions. The measurements took place on two different field sites of a Bioforsk experimental farm under consideration of two tillage treatments (conservation and conventional). Aim of the investigation was to quantify the influence of tillage and with this different topsoil conditions on stress impact and soil properties.

S03.01-P -19

MACRONUTRIENT INPUT THROUGH LITTER IN A RIPARIAN FOREST ON DIFFERENT BRAZILIAN SOILS

Soares Marcio Roberto*^[1], Casagrande José Carlos^[1], De Souza Oliveira Mariane^[1], Impulcetto Monteiro De Moraes Murilo^[1]

^[1]Federal University of São Carlos ~ Department of Natural Resources and Environmental Protection ~ Araras ~ Brazil

The litter is particularly important for acting on the soil surface as a system of nutrient cycling, accumulating vegetal material that decompose and supply the soil and roots with nutrients and organic matter, which is essential in restoring soil fertility in degraded areas. This study was conducted in two tracts of riparian ecosystems of 2 ha each, composed of two populations of semideciduous mesophytic forest, and an agroecosystem cultivated with sugar cane. The forested areas differ in age [9 (recent forest - RF) and 18 years (old forest - OF)] and in soil type [Typic Hapludox (TH) and Arenic Hapludult (AH)]. Total litter produced in old and recent riparian forests on TH was, respectively, 10.5 ton ha⁻¹yr⁻¹ and 13.6 ton ha⁻¹yr⁻¹, while on AH was 10.1 ton ha⁻¹yr⁻¹ in old forest and 11.1 ton ha⁻¹yr⁻¹. The average time of renewal of forest litter in recent and in old forest was estimated at 0.77 yr and 0.57 yr. In our experiment, we obtained the following range of N, P, K, Ca and Mg, consecutively: 159-278; 11,4-15,5; 27,8-43,9; 164,6-265,2 and 20,7-30,5 kg ha⁻¹ year. The amount of nutrients contributed by litter varied according to the total mass of litter produced, in higher quantity in the recent forests in comparison with the old forest, regardless soil type. In the recent forests, the cycling of nutrients occurred more quickly. Since in the old forests, this time was larger, providing nutrients more slowly, indicating a better equilibrium and sustainability of the forest.

S03.01-P -20

MAPPING DEGRADATION AND CONSERVATION IN 16 STUDY SITES OF THE DESIRE PROJECT

Van Lynden Godert^{*[1]}

^[1]ISRIC - World Soil Information ~ none ~ Wageningen ~ Netherlands

The World Overview of Conservation Approaches and Technologies initiative (WOCAT) started in 1992, in reaction to the Global Assessment of Soil Degradation (GLASOD) by ISRIC. The original idea of WOCAT was to develop a world map similar the GLASOD one, however showing the positive side, i.e. describing what achievements had been made to combat soil degradation. Since 1992 WOCAT has developed and tested a method for standardized documentation and evaluation of Sustainable Land Management (SLM). It comprises three questionnaires, for documenting “Technologies” (what is actually implemented in the field), “Approaches” (what is needed in terms of “enabling environment” for a successful implementation of a technology) and a mapping questionnaire. The resulting database currently counts more than 350 technologies and over 250 approaches from around 50 countries. In the DESIRE project the WOCAT mapping tool was used to map area coverage, degree, impact, effectiveness, and other parameters of land degradation and conservation for 16 study sites. The mapping method in the study sites complements the information provided by the individual case studies on technologies and Approaches. It evaluates what type of land degradation is actually happening where and what is done about it in terms of Sustainable Land Management (SLM). The on-line map database is hosted by WOCAT, and the mapped outputs that can be generated from this database provide a powerful tool to obtain an overview of land degradation and conservation in a country, a region, or worldwide.

PEDO-ECOLOGICAL PATCHINESS AS AFFECTED BY ROCK FRAGMENTS IN SEMIARID RANGELANDS

Pariente Sarah*^[1]

^[1] Bar-Ilan University ~ Laboratory of Soil and Geomorphology, Department of Geography and Environment ~ Ramat Gan ~ Israel

The research aims were: (a) to investigate the effects of RF, of divers sizes and in various positions, on soil temperature, and moisture, organic matter, and calcium carbonate contents; (b) to study the effects of hillslope aspect on the above properties of soil underneath RF; and (c) to assess the ecological benefits of RF. On north- and south-facing hillslopes in the northern Negev region of Israel, soil was sampled from beneath RF of divers sizes – small, medium, and large, i.e., 4-6, 8-10, and 13-16 cm, respectively – that were positioned on the soil surface or partially embedded in the soil. Control samples were taken from bare soil. For each soil sample, the various soil properties were determined. The rock fragment characteristics affected the various soil properties with differing intensities. Under the large and medium RF soil moisture contents were significantly higher than those under the small ones; and embedded RF promoted higher moisture contents than those on top of the soil. RF position had the most significant effect on soil organic matter content, which was higher under "on top" fragments. Rock fragment size and position had significantly greater effects on the south-facing than on the north-facing hillslopes, with regard to increasing the spatial variability of soil temperature, and moisture and organic matter contents. Variations in soil properties were associated with the RF, which can be seen as fertile micro-islands, i.e., concentrating natural resources and releasing them to the environment, and forming potential habitats for varied fauna and flora.

S03.01-P -22

PENETROMETER RESISTANCE AS AFFECTED BY CROP SEQUENCE AND MECHANICAL DECOMPACTION IN A DEGRADED SOIL IN THE ARGENTINE PAMPAS.

Gerster Guillermo Raúl^[1], Bacigaluppo Silvina^[1], Bodrero Marcelo^[2], Salvagiotti Fernando^[2]

^[1]INTA ~ Suelos. Extensión Agrícola ~ Oliveros ~ Argentina ^[2]INTA ~ Agronomía ~ Oliveros ~ Argentina

In the Argentine Humid Pampas region, soybean is mostly planted as monoculture under no tillage in silty-loam soils. Under these conditions, subsurface soil compaction mainly due to agricultural traffic is commonly observed. In order to break compacted layers, the inclusion of cereals in the rotation as well as deep tillage (i.e. up to 30 cm depth) has been suggested, but results have been inconsistent, especially with the latter option. The aim of this study was to analyze the effects of deep tillage and crop sequence on penetrometer resistance. The experiment began in 2006 on a silty-loam soil (typic Argiudoll). Treatments consisted of two crop sequences (Soybean-Soybean and Maize-Soybean-Wheat/soybean) combined with (up to 27 cm) and without deep tillage. In 2009, 2010 and 2011, mechanical penetration resistance (MPR), up to 40 cm depth, was measured at 2.5 cm intervals. Mechanical decompaction and cereal inclusion in the crop rotation reduced MPR and no interaction between deep tillage and crop sequence was observed in any depth. In 2009 and 2010, deep tillage showed lower MPR between 7.5 cm and 25 cm depth. The inclusion of cereals in the rotation showed significant differences below 25 cm in 2009 and below 10 cm in 2010. In 2011, MPR reductions were observed in the whole analyzed profile in response to cereal inclusion and also to deep tillage. These results suggest that a long term response of deep tillage may be associated with root proliferation below 25 cm.

S03.01-P -23

PHYSICAL PROPERTIES OF VOLCANIC ASH SOILS IN SOUTHERN CHILE

Neumann Patrick^[2], Fleige Heiner^[2], Horn Rainer^[2]

^[1]Institute of Plant Nutrition and Soil Science ~ Soils Science ~ Kiel ~ Germany ^[2]Institute of Plant Nutrition and Soil Science ~ Soil Science ~ Kiel ~ Germany

Depending on climate conditions and stage of soil development, soils affected by volcanic ashes belong to the most productive soils in the world. In southern Chile (40° S), they are widespread and, thus, form the basis of intensive agricultural use. As a function of the distance between the volcanoes emitting fly ashes and the affected areas, soils vary due to texture and age of the primary material and show development gradients. Therefore, younger soils close to the volcanoes can be classified as Regosols, while with increasing distance, Andosols can be found more often. To find out about the changes in soil mechanical stability and soil functionality due to weathering stage, soil samples were taken from different profiles along a catena representing different stages of soil genesis. Beside soil genesis also different intensities of land use (secondary forest, meadow, and cropland) can influence soil hydraulic and mechanical properties such as saturated hydraulic conductivity (k_s), air conductivity (k_a), dry bulk density (ρ_t), porosity (e), and precompression stress value (P_v). In addition to these properties organic matter content (OM) was analyzed. We found that an increase in land use intensity may lead to a decrease in k_s and k_a as well as to an increase in ρ_t and P_v . While e declines, the fraction of middle pores increases due to the loss of macro pores. This leads to a decrease in air capacity, while field capacity increases. Furthermore, as a consequence, OM content decreases.

S03.01-P -24

RECOVER OR ORGANIC CARBON AND NITROGEN BY REVEGETATION OF A DEEPLY EXCAVATED OXISOL DURING 19 YEARS

Dos Santos Batista Bonini Carolina^{*[1]}, Paz Gonzalez Antonio^[2], Alves Marlene Cristina^[1]

^[1]São Paulo State University ~ plant protection, agricultural engineering and soil ~ Ilha Solteira ~ Brazil ^[2]University of Coruna ~ Biology ~ La Coruña ~ Spain

The objective this study was to quantify the organic carbon and nitrogen 9 and 19 years after revegetation of an abandoned area, resulting from deep excavation of an Oxisol, by the construction of hydroelectric power plant, recovering nineteen years ago with lime, gypsum and green manure. The studied area is located in Mato Grosso do Sul, Brazil. The experimental design was a completely randomized with seven treatments and four repetitions. The treatments were: control (tilled soil without culture); *Stizolobium aterrium*; *Cajanus cajan*; lime+*S. aterrium*; lime+*C. cajan*; lime+gypsum+*S. aterrium*; lime+gypsum+*C. cajan*. In 1994, all treatments with *C. cajan* were replaced by *Canavalia ensiformis* and in 1999, *Brachiaria decumbens* was implanted in all treatments. Data from vegetated treatments were compared with the control bare soil. Soil organic carbon and nitrogen were determined by elemental analyzer. Samples were collected at 0.00-0.10, 0.10-0.20 and 0.20-0.40m depth, in 2001 and 2011. The results were analyzed by analysis of variance, following Scott-Knott test (5%) of probability to compare averages. Mean values for C and N at the 0-0.10 cm depth were 0.24% and 0.015% in 2001 and 0.53% to 0.060% in 2011, respectively. Therefore C and N topsoil contents increased 2 and 4 times respectively during the last 10 years. Moreover, in 2001, C and N of the vegetated plots didn't differ statistically from the control, whereas in 2011 significant differences were found. It was concluded that green manure was efficient for increasing organic carbon and nitrogen in the topsoil, initiating recover of soil profile differentiation.

Glomalin is a high molecular weight insoluble glycoprotein stored in great quantity in the cell wall of the hyphae of arbuscular mycorrhizal fungi (AMF); once released outside it is able to improve soil fertility by slowing the degradation of organic matter and the associated nutrient loss, through the stabilization, via hydrophobic interactions, of aggregates that physically protect the particulate matter from the activity of enzymes. The aim of this work was to investigate the possible correlation between glomalin (or glomalin related soil proteins, GRSP) and the concentration of water stable aggregates (WSA), in two adjacent olive groves located in Basilicata (Italy) and managed for 11 years according to different horticultural model (conventional and sustainable). The sustainable farming model provided a drip irrigation system with treated urban wastewater, spontaneous cover cropping and light annual pruning, with resulting material left in the field. The conventional system provided plants growing under rain-fed conditions, shallow tillage, mineral fertilization carried out once a year and biennial heavy pruning. Soil sampling was performed at four depths between the trees in the line and between the lines for three replies per thesis. WSA resulted to be a highly sensitive indicator of the effect of soil management on soil structuration (especially in the "macro" fraction) showing the highest statistically significant values in the sustainable system. The highest concentration of glomalin was found in the first 20 cm layer of the conventional model probably due to the disruption of the mycelium provoked by the mechanical tillage.

RUNOFF AND SOIL EROSION CONTROL WITH PAM AND FOREST RESIDUE MULCHING AFTER FOREST FIRES IN PORTUGAL.

Prats Alegre Sergio^[1], Martins Martinho Antonio Santos^[1], Faria Sílvia Regina*^[1], Keizer Jan Jacob^[1]

^[1]Centre for Environmental and Marine Studies (CESAM) ~ Department of Environment and Planning, University of Aveiro. ~ Aveiro ~ Portugal

The surface affected by wildfires in Portugal had grown in the last decades and could increase following the foreseen future climate change scenarios. Wildfires lead to an increase in overland flow and soil erosion in burned areas. Post-fire stabilization treatments, such as mulching and the new and easy-to-use polyacrilamide (PAM), have been pointed out by many authors as some of the best techniques to relieve these impacts. This study evaluates the effectiveness of chopped bark mulch, applied at a rate of 13,6 Mg ha⁻¹ (80% of cover), and PAM, at a rate of 0,05 Mg ha⁻¹, for reducing surface runoff and erosion in an eucalyptus plantation at two scales: microplot (0,24m²) and slope (100m²) in northern Portugal. After the first year (mean precipitation 1442 mm), the control plots showed 45% of runoff coefficient at microplot scale, and 2,5% at slope scale. Soil erosion was 7,8 Mg ha⁻¹ and 0,81 Mg ha⁻¹ for small and slope scale respectively. The treatment with chopped bark mulch reduced runoff by 55% and sediment loss by 90% on both scales. The PAM treatment reduced runoff by 20% but wasn't effective for sediment loss reduction. Besides the mulch treatment, plot size and position on the slope proved to be important factors in the hydrological and erosive response as a consequence of hydrologic connectivity, fire intensity and ground cover.

**SALINIZATION LEVELS OF SOIL AND WATER IN A MEDITERRANEAN COASTAL WETLAND:
THE PEGO-OLIVA MARSH (SPAIN)**

Gimeno-García Eugenia*^[1], Pascual-Aguilar Juan Antonio^[1], Rubio Jose Luis^[1], Andreu Vicente^[1]

^[1]Centro de Investigaciones sobre Desertificación-CIDE (CSIC, UV, GV). ~ Degradacion y Conservacion de Suelos ~ Moncada ~ Spain

In the last decades, the increases of the anthropogenic pressure and the related socio-economic development have provoked important changes in Mediterranean coastal wetlands, through drainage for cultivation, construction and development of infrastructures, irrigation systems, etc. These transformations lead to the degradation of this high status ecological habitats (destruction of flooding prairies, riparian habitats and breeding areas), with also important repercussions on soil and water quality. This study is focused on the evaluation of soil and water quality parameters related to salinization in the Pego-Oliva coastal wetland (1250 hectares), a Natural Park in the Valencia Community (Spain), also included in the RAMSAR Agreement. In this area, 46 soil samples from three land uses (rice farming and marsh area, citrus crops and shrubland soils), and 67 water samples from different sources (ditches and irrigation channels, lake, rivers, groundwater) were analysed. The soil and water quality parameters studied were electrical conductivity (EC), sodium and chloride ion concentrations, and sodium from the soil exchangeable complex (ESP). Main results show that 24% of soil samples have $EC > 4 \text{ dS m}^{-1}$, all of them coming from the rice farming and marsh areas. These soils showed mean ESP of 26.5%, with values up to 78%. However, the other land uses did not exceed the ESP of 5%. Regarding waters, 82% of samples presented $EC > 2 \text{ dS m}^{-1}$, and sodium and chloride concentrations higher than 200 mg L^{-1} were found in the 85% of samples. Attending their sources, the highest values were obtained from the lake and ditches waters.

SOIL COMPACTION SUSCEPTIBILITY: TUNING OF A NEW ESTIMATION INDEX

Pellegrini Sergio*^[1], Vignozzi Nadia^[1]

^[1]CRA ~ CRA-ABP Research Centre for Agrobiological and Pedology ~ Firenze ~ Italy

Soil compaction due to the ever-growing size and power of agricultural machinery is commonly considered one of the main causes of decreasing soil productivity and environmental degradation. Compaction susceptibility was assessed by the model of Smith et al. (1997), having as input data the silt plus clay percentage. The model validation was performed through the determination of soil compressibility index (C); uniaxial compaction tests were carried out on air-dried and sieved (2 mm) samples of 16 soils from different geographic areas of Italy under different soil use (arable, orchard, pasture and natural vegetation). C represents the slope of the linear portion of the relationship between bulk density (ρ_b) and the decimal logarithm of applied pressure. Soil samples were moistened and equilibrated at 3 different water contents: field capacity (-33 kPa), 110% and 90% (w/w) of plastic limit (1.1PL and 0.9PL, respectively). Four different pressures (50, 100, 200 and 400 kPa) were then applied by means of a hydraulic press. Results show that C , since it represents the average slope of the compression lines for a range of water contents, does not attribute adequate significance to the bulk density values resulting from the compaction tests. This may lead to an inconsistent assessment of real soil compaction susceptibility. In order to improve the representativeness of C , a modification was made by the addition of the bulk density values resulting from an applied pressure of 100 kPa ($\rho_{b100kPa}$). Such corrected C values (C_{cm}) better describe the compaction behaviour of soils.

SOIL DEGRADATION AND DESERTIFICATION IN THE MEDITERRANEAN: PROBLEMS AND POSSIBLE SOLUTIONS

Rubio Jose Luis*^[1]

^[1]Centro de Investigaciones sobre Desertificación-CIDE (Consejo Superior de Investigaciones Científicas, Generalidad Valenciana, Universidad de Valencia) ~ Immediate Past President of the European Society for Soil Conservation-ESSC ~ Moncada, Valencia ~ Spa

Soil Degradation-Desertification is an important menace to the capacity of Mediterranean terrestrial ecosystems to provide services, biomass production and ecological functions. In the last decades dramatic land use changes occurred in many parts of the Mediterranean countries driven by crisis of traditional agriculture and associated land set aside. Both the abandon of cultivation and the abandon of maintenance of soil conservation structures originated the loss of soil capacity to buffer extreme climate events like torrential rains or drought periods. The socioeconomic changes influenced the increase of forest fires together with the concentration of human activities in coastal areas (littoralization). The consequences of such enormous pressures and the sealing effect of urbanization are the irreversible loss of very productive soils and the disruption of the infiltration and run-off pattern. Climate change and aridification trend will also exacerbate the unsustainable exploitation of water resources leading to serious environmental damage to land, including chemical and organic contamination, salinization and marine intrusion on coastal aquifers. The current schemes of soil conservation should be expanded to include new perspectives and implications in the context of the sustainable use of terrestrial ecosystems. The demands for the maintenance of biodiversity, carbon cycle regulation, food production, regulation of water resources, landscape maintenance and preventing land degradation require new paradigms in the protection of the soil to be developed under the prospects of multiuse and multifunctionality. Soil is a key and complex natural resource demanding urgent and comprehensive policy protection addressed by the European Commission and the Member States.

SOIL DEGRADATION INDUCED BY THE CHANGE IN MANAGEMENT OF THE “ARENADOS” SYSTEM (LANZAROTE, CANARY ISLANDS)

Tejedor Marisa^[1], Díaz Francisco^{*[1]}, Dorta María Ascensión^[1], Hernández-Moreno Jose Manuel^[1], Jiménez Concepción^[1]

^[1]Universidad de La Laguna ~ Edafología y Geología ~ La Laguna ~ Spain

Lanzarote is one of the most arid zones of the EU. Dryland agriculture could be developed thanks to a traditional agrosystem called “arenados”, which rely on the use of basaltic tephra mulch. Recently, the availability of new water resources: desalinized seawater and reclaimed municipal water, has generated new expectations for higher agricultural productivity. As a consequence, irrigation has been introduced to the traditional agrosystems. The aim of this study was to evaluate the quality of the irrigation waters and its impact on soil properties. Eighty irrigated field plots were selected, along with their non-irrigated counterparts. Fifty plots were irrigated with desalinized water and thirty with reclaimed municipal wastewater. Irrigation water was sampled periodically. The irrigated soils showed an increase of salinity, especially in the case of wastewater irrigation. The main problem observed was the accumulation of boron in soils, in some cases, at potentially toxic levels. The results showed that water management practices are applied without proper knowledge of the soil–water dynamics of the mulched soils. This, together with a better control of water quality are essential requirements to prevent mid-term soil degradation leading to situations hardly recoverable. It is important to attain the sustainability which characterizes the dryland agrosystem.

SOIL PHYSICAL PROPERTIES UNDER DIFFERENT CROPPING SYSTEMS IN ESTONIA

Sánchez De Cima Diego^{*[1]}, Reintam Endla^[1], Luik Anne^[1]

^[1]Estonian University of Life Sciences ~ Soil sciences ~ Tartu ~ Estonia

A five years crop rotation system (pea, potato, barley, red clover and winter wheat) based on 80 plots was conducted at the experimental station of Estonian University of Life Sciences in Eerika, Tartu (Estonia) since 2008. From those plots, 40 were cultivated under conventional farming system with different concentrations of mineral fertilizers, and 40 under organic farming conditions and winter oil-rape, winter rye, winter wheat, ryegrass and under seeding as rotating crops. From these, 20 of them were under cover crops (organic I), and for the other 20 (organic II), manure were added. A total of 320 samples taken (4 replications per plot), taken in October 2010 and October 2011, respectively. From these samples, penetrability, field water retention capacity, porosity, air filled pores, and water permeability were studied respectively. Results doesn't show any no significant difference between organic and conventional management for penetration resistance and water permeability, but results of 2011 show an increase in the penetration resistance especially in the conventional plots in comparison with the organic ones and comparing the different crops under the four systems from 2011, barley us. and w. wheat presented a higher penetration resistance in comparison with the other cultures. Analysis from 2010 show differences in porosity and air filled pores within the organic plots, where w. wheat + ryegrass and pea + oil rape had higher values. In the case of water permeability the plots under conventional treatment shown higher values in comparison with the organic ones.

S03.01-P -32

SOIL QUALITY AND PRODUCTIVITY LOSSES DUE TO COMPACTION IN ESTONIAN GRASSLANDS

Reintam Endla*^[1], Krebstein Kadri^[1], Sanchez De Cima Diego^[1], Köster Tiina^[1]

^[1]Estonian University of Life Sciences ~ Department of Soil Science and Agrochemistry ~ Tartu ~ Estonia

Identifying the vulnerability of soils to compaction damage is becoming an increasingly important issue when planning and performing farming operations. Although grassland species are more resistance to soil compaction, the yield losses occur also there due to repeated overriding. In conventional agriculture the whole field is passed usually more than once and field edges even 8 to 10 times. However, the losses of plant biomass may not be remarkable high, but soil compaction affects also the quality of the production and soil. The field experiments with different grassland species at different compaction and fertilization levels and farm field survey were conducted in Estonia in time period 2008–2011. Soil physical and chemical properties, such bulk density, porosity, penetration resistance, water content and permeability, pH, available P, K, Ca, Mg, total N and organic C content were measured. From plant analyses the plant shoots and roots biomass, yield and their nutrient content was measured. The results revealed the reduction of grassland plants productivity up to 80% due to continuous compaction in the experiment on sandy loam soil. On the farm grasslands the average reduction of the aboveground biomass during one season was 20% in the tyre traces and field edges. However, even the compaction did not affect the biomass of the plants; it decreased the nutrient content of plants. Mainly the losses of plant productivity were connected with lower soil aeration in wet years and higher penetration resistance and amount of plant unavailable water in dry years.

**SOIL QUALITY EVALUATION UNDER AGRO-SILVO-PASTORAL MEDITERRANEAN
MANAGEMENT SYSTEMS**

Ledda Luigi^[1], Doro Luca^[1], Madrau Salvatore^[2], Francaviglia Rosa^{*[3]}

^[1]University of Sassari ~ Dipartimento di Scienze Agronomiche e Genetica Vegetale Agraria ~ Sassari ~ Italy

^[2]University of Sassari ~ Dipartimento di Ingegneria del Territorio, sezione di Geopedologia e Geologia applicata ~ Sassari ~ Italy

^[3]Consiglio per la Ricerca e la Sperimentazione in Agricoltura ~ Centro di Ricerca per lo Studio delle Relazioni tra Pianta e Suolo ~ Rome ~ Italy

According to Franzluebber (2002) the degree of stratification of soil organic C and N, as well as other parameters, with soil depth, expressed as a ratio, can indicate soil quality or soil ecosystem functioning and sustainability under different agricultural management. Stratification ratios > 2 indicate a higher soil quality and contribution to agriculture sustainability. A case study from north-eastern Sardinia (Italy) is presented. Agriculture is mainly extensive and markedly agro-silvo-pastoral, and is typical of similar areas of the Mediterranean basin. The following land uses were considered: tilled vineyards established in 1994 (TV), no-tilled grassed vineyards established in 1991 (GV), hay crop (oats, Italian ryegrass and annual clovers or vetch) with sparse cork oaks (HC), pasture, covered with spontaneous herbaceous vegetation with sparse cork oaks (PA), semi-natural systems (scrublands, Mediterranean maquis and Helichrysum meadows), former vineyards set-aside about 30 years ago (SN), forest (Quercus suber L.) established in the past century (CO). The tilled vineyards and no-tilled grassed vineyards are agricultural higher intensive land uses, whereas hay crop, pasture, semi-natural and forest are agro-silvo-pastoral lower intensive land uses. Data are discussed in terms of soil organic C and total N levels in g kg⁻¹, and stratification ratios calculated from contents in the 0-20 cm soil layer divided by that in the 20-50 cm.

S03.01-P -34

SOIL QUALITY INDEX TO COASTAL PLAIN ECOSYSTEM FOREST

Casagrande José Carlos^[1], Bonilha Rodolfo Martins^[1], Soares Marcio Roberto^[1], Reis-Duarte Rose Mary^[1], Cunha Joana América Castellar Da^[1]

^[1]Agrarín Sciences Center/Federal University of São Carlos ~ Natural Resources and Environmental Protection ~ Araras ~ Brazil

In recent decades, with growing concern about natural resources and environmental quality, intensified research, resulting in the definition of soil quality (SQ), strongly rooted in the concept of sustainability. To this aim, several models have been proposed in attempt to assess the Soil Quality Index (SQI). The coastal plain ecosystem (Restinga forest) is associated with rain forest (Mata Atlântica), and is the most fragile and susceptible to human disturbance. The aim of this study is to determine the Soil Quality Index for Restinga forest, to high and middle stages of vegetation regeneration and soil without vegetation, based on their chemical, physical and microbiological attributes. It was developed in four locations of São Paulo state: (1) Anchieta Island, Ubatuba, (2) Juréia-Itatins Ecological Station, Iguape, (3) Vila das Pedrinhas, Comprida Island; and (4) Cardoso Island, Cananéia. The soil samples were collected at a depth of 0 to 10 cm for chemical, physical and microbiological analysis, and also evaluated the distribution of the root system into the soil profile. It was used the Comparative Additive Model to SQI determinations. The SQI values obtained for all studied areas demonstrated low production potential biomass of these soils, as well as its low resilience; SQI similar values (0,1 a 0,3) to the forests with and without vegetation showed that Restinga forest is edaphic; the use of routine chemical analysis is sufficient to determine the SQI to this ecosystem.

S03.01-P -35

SOIL QUALITY RECOVERY FOLLOWING NATURAL VEGETATION SUCCESSION AFTER LAND ABANDONMENT

Frederique Kirkels^[1], Van Der Meulen Maaïke^[1], Cammeraat Erik^{*[1]}, Seijmonsbergen Harry^[1]

^[1]University of Amsterdam ~ IBED-Earth surface science ~ Amsterdam ~ Netherlands

Abandonment of agricultural fields is a wide-spread phenomenon on the southern slopes on the island of Tenerife (Spain). Land abandonment has negative environmental impacts because of its close relation with soil degradation especially in the early stages of abandonment when vegetation recovery is only at its initial state. Focus of this research is to study the rate of soil recovery after the abandonment of agricultural practices, and trying to shed some light on the still poorly understood relationship and interactions between vegetation and soil development. The research was carried out near the village of Villaflor, an area where agricultural field abandonment is abundant on sloping areas. Soil degradation/regeneration in abandoned agricultural fields has been evaluated for fields belonging to different age groups of abandonment with comparable soil types. Soil quality was evaluated using simple parameters (slope angle, exposition, soil organic matter content, aggregation, texture, vegetation cover and species). We found significant correlations between aggregate stability, clay content, organic matter, slope angle and number of plant species. Aggregate stability and organic carbon content showed a non-asymptotic development over time. Surprisingly, we observed a drop in aggregate stability between 10-20 years after abandonment, after which the stability increased again and additional research is required to explain these results. However the results obtained provide valuable information about the sensitivity of aggregate stability as an indicator for soil quality restoration and degradation vulnerability in relation to revegetation.

S03.01-P -36

SOIL RESISTANCE TO PENETRATION OF AN OXISOL IN RECOVERY BY 19 YEARS

Dos Santos Batista Bonini Carolina*^[1], Alves Marlene Cristina^[1], Marchini Débora De Cássia^[1], Souto Filho Sebastião Nilce^[1], Arruda Otton Garcia De^[1]

^[1]São Paulo State University ~ plant protection, agricultural engineering and soil ~ Ilha Solteira ~ Brazil

The objective this paper was to evaluate the soil resistance to penetration of a degraded Oxisol after 19 years in recovery. The area studied is located in the state of Mato Grosso do Sul, Brazil, and the soil studied is an Oxisol degraded by the construction of hydroelectric power plant is recovering 19 years ago with lime, gypsum and green manure. The experimental design was a completely randomized with seven treatments and four - replication. The treatments were: mobilized soil (tilled soil without culture); Stizolobium aterrium; Cajanus cajan -until 1994 and then substituted by Canavalia ensiformis; lime+S. aterrium; lime+C. cajan until 1994 and then substituted by C. ensiformis; lime+gypsum+S. aterrium; lime+gypsum+C. cajan until 1994 and then substituted by C. ensiformis. In 1999, all treatments were implanted Brachiaria decumbens. The data were compared with two control: exposed soil and native vegetation of the Savannah . Were determined the soil resistance to penetration and soil moisture in the depths of 0.00-0.10, 0.10-0.20 and 0.20-0.40m, in year 2011. The results were analyzed effectuating the analysis of variance, Scott-Knott test to 5% of probability to compare averages. The highest and lowest values of soil resistance to penetration were found to control, degraded soil and native vegetation of Savannah , respectively. The values of soil resistance to penetration decreased recovery treatment in relation to soil degradation and show that the soil is in the process of recovery. The treatments are effective in recovering soil for this indicator of soil quality.

SOIL SALINITY ASSESSMENT IN THE NERETVA RIVER FLOODPLAINS

Zovko Monika^[1], Romic Davor^[1], Ondrašek Gabrijel^[1], Romic Marija^[1], Filipovic Vilim^[1], Bakic Helena^[1]

^[1]University of Zagreb, Faculty of agriculture ~ Department of soil amelioration ~ Zagreb ~ Croatia

Environmental degradation in the coastal areas is a current problem in some regions of the Adriatic coast and it is mainly related to the soil and water salinization, very serious threats to the ecosystems and causes of desertification. The Lower Neretva region (Croatia) is intensively used for agriculture, and it is at the same time environmentally highly sensitive. A major threat to disturbing the balance of the agricultural ecosystem is the salinization of water and soil. Rational management of soil salinization requires an understanding of how soil salt concentrations vary across the land. The general goal of this research was to identify and map the salinity of soils in a geographically defined area of 5,815 ha of the Lower Neretva region. In order to identify the spatial variability of soil salinity in the surface layer (0-25 cm), topsoil samples (0-25 cm) were collected from 246 locations using a systematic sampling on a 500-m grid. Subsoil samples (25-50, 50-75, 75-100 cm) were collected from 63 locations using a systematic sampling on a 1000-m grid. Electrical conductivity as well as sodium and chloride concentrations measured in the saturated soil extract show high variability of soil salinity level. High variability of the soil salinity level in both horizontal and vertical spatial dimensions was identified through statistical and geostatistical analyses and mapping. An intermediate scale map may be useful in delineating specific areas where soil salinity may be problematic for agriculture, wetland habitats and other natural habitats in the Neretva valley.

S03.01-P -39

SOIL SECURITY - PRIORITIZING GLOBAL UNDERSTANDING OF SOIL DEGRADATION AND ITS AMELIORATION

Koch Andrea^{*[1]}, Mcbratney Alex^[2]

^[1]United States Studies Centre at the University of Sydney ~ Sustainability ~ Sydney ~ Australia ^[2]University of Sydney ~ Faculty of Agriculture Food and Natural Resources ~ Sydney ~ Australia

Soil degradation is a largely silent phenomenon. Left unaddressed it will lead to catastrophic consequences. Yet bringing the attention of society to this major threat is very difficult. Soil is silent in most cultures, even though soil provides the ecosystem services upon which life on earth depend. What is required is a conceptual term that encapsulates the threat but at the same time communicates the required response and the benefits of the response. It must be something that grabs the attention of scientists, policy makers and land managers. It must be simple enough to communicate and be recognized by the general public at local and global scales. It must be easily translated into policy and into practice. "Soil security" is a new term that achieves this requirement. Soil security is the maintenance or improvement of the world's soil resource so it can provide sufficient food and fibre, fresh water, contribute to energy sustainability and climate stability, maintain biodiversity and overall environmental protection and ecosystem services. For soil to be secure it must maintain its function. Soil carbon is a key indicator of soil function. Therefore a principal mechanism for achieving soil security is the management and sequestration of soil carbon through active land management systems and technologies. Soil security can be achieved by increasing and managing soil carbon in the world's soils. The science, technology and management practices already exist to achieve this. By taking a new lens through soil security, the threat of soil degradation can be reversed.

S03.01-P -40

SOIL STRUCTURE IN THE MAIN ECOSYSTEMS OF THE MEDITERRANEAN ISLE OF PIANOSA, ITALY

Pini Roberto^{*[4]}, Manuele Scatena^[4], Rosalba Risaliti^[2], Dodero Alessandro^[3], Pezzarossa Beatrice^[4]

^[1]Istituto per lo Studio degli Ecosistemi ~ CNR ~ Pisa ~ Italy ^[2]Centro Interdipartimentale di Ricerche Agro-Ambientali "Enrico Avanzi" ~ University of Pisa ~ Pisa ~ Italy ^[3]Istituto per lo Studio degli Ecosistemi, Sede di Firenze ~ CNR ~ Firenze ~ Italy ^[4]Istituto per lo Studio degli Ecosistemi, sede di Pisa ~ CNR ~ Pisa ~ Italy

The Isle of Pianosa is a typical Mediterranean ecosystem. Past agricultural activities had a strong impact on the original vegetation, which is believed to have been a Mediterranean macchia. After being abandoned, the agricultural land is undergoing re-naturalization. We studied the effects of both the different land use and the cessation of agricultural activities on soil structure in natural Mediterranean macchia (M), arable fields (A), and permanent pasture land (P). The organic carbon content was highest in M and lowest in A. [[Porosity data indicated that]] the soil was moderately porous, irrespective of the land use. Modifications in land use from natural macchia to human activities compacted the soil, with pasture and tillage reducing the overall volume of pores that retain water available for plant and microorganisms. The three vegetation systems showed similar values of the total amount of pores greater than 50 mm, but the amount of the largest pore classes increased in the order: M, P, and A, in all cases mainly due to the increasing presence of elongated pores. Total cracking increased significantly from M to P to A. However, the total length of cracks moved in the opposite direction (M>P>A). More numerous and thinner cracks were formed in M, and fewer larger cracks in A. There was an intermediate condition in P. These data indicate that soil finds it more difficult to regenerate a good structure when the land use leads to a decrease in organic carbon content.

SURVEY OF THE EFFECT OF PLANTS ON SOIL PROPERTIES AND STABILIZATION (CASE STUDY: SEMNAN-IRAN)

Zehtabian Gholamreza*^[1], Nazeri Khashayar^[1], Masoudi Reyhaneh^[1], Khosravi Hasan^[1]

^[1]University of Tehran ~ Faculty of Natural Resources ~ tehran ~ Iran, Islamic Republic of

*Survey of the effect of plants on soil properties and stabilization (case study: Semnan-Iran) Gh. Zehtabian¹, KH. Nazeri², *R. Masoudi³, H. Khosravi³ Iran is located on desert belt of the world and it has arid and semi- arid climates. So most of the areas expose to desertification and degradation of desert ecosystem. Wind is one of the most important reasons of erosion in arid region and using vegetation cover is one of the best ways of soli stabilization in these areas. The main aim of this study is survey of the effects of plant such as calligonum sp, on soil physic- chemical properties in sand dune of Semnan, so that positive effects are introduced and is prevented from expansion of Desert. at the first place, two main areas were selected and soil samples were, then, taken from beneath bushes and between bushes. After sampling, some factors such as organic matter, n, ph, clay and silt percentage were calculated and then the obtained results were analyzed by MSTAT statistical software. Considering the analysis of data, significant differences were observed between treatments. The result showed organic matters, N and PH increase in soil of beneath bushes comparison with soil of between bushes; also some physical factors like clay and silt percentage are so. As a result, creation of vegetation cover can have many positive effects on soli and ecological properties moreover they can reform unstable soil as sand dunes. Keywords: soil properties, vegetation, organic matter, wind, Iran*

SUSTAINABLE MANAGEMENT SYSTEMS AFFECT TOPSOIL PHYSICAL PROPERTIES AND ORGANIC C CONTENT IN A HIGH DENSITY OLIVE ORCHARD

Vignozzi Nadia^{*[1]}, Pellegrini Sergio^[1], Pagliai Marcello^[1], Caruso Giovanni^[2], Gucci Riccardo^[2]

^[1]CRA ~ CRA-ABP Agrobiology and Pedology Research Centre ~ Firenze ~ Italy ^[2]University of Pisa ~ Dept. Coltivazione e Difesa delle Specie Legnose ~ Pisa ~ Italy

In recent years there is evidence of an increasing occurrence of heavy rainfall events associated with climate changes, that further expose the soil to erosion and flooding. One of the main aspect of soil degradation is crusting, due to the impact of raindrops when the soil is bare and dry. In spite of all these problems, periodic tillage is still the most commonly adopted method to control weeds in olive orchards. The aim of this study was to evaluate the effect of two conservative soil management practices, namely minimum tillage (MT) and natural grass cover (NC), on soil characteristics and tree performance in a high density, deficit-irrigated olive orchard on a Typic Haploxeralf sandy loam soil. We compared soil macroporosity, water infiltration rate, different fractions of organic carbon five years after the beginning of the trial, and yield components over five years. Soil macroporosity in the upper layer of NC management was significantly higher than MT, which had very low values (2%). Water infiltration rate in MT plots was much lower than in NC ones, because of soil surface crusting. NC also had higher values of total organic carbon (TOC) and total exchangeable carbon (TEC) than MT, whereas the humic carbon (HC) fraction was unaffected by soil management. Yield components were differently affected by soil management: the number of fruits of the NC plots was significantly lower than that of MT, whereas the oil content in the mesocarp was similar for both treatments.

S03.01-P -43

THE CONTRIBUTION OF KEY MICROORGANISMS FOR RESTORING SOILS FROM FORMER COAL MINING SITES

Gutknecht Jessica*^[1], Huth Am Maximiliane^[2], Auge Harald^[2], Freitag Elisabeth^[1]

^[1]Helmholtz-Centre for Environmental Research ~ Department of Soil Ecology ~ Halle ~ Germany ^[2]Helmholtz-Centre for Environmental Research ~ Department of Community Ecology ~ Halle ~ Germany

Remnant soils from coal strip-mining, such as in central Germany, are very nutrient poor and are thus a challenge to re-vegetate or restore. In this study we examine how key microbes (mycorrhizal fungi and N-fixing bacteria) and plant species composition can best be combined to restore soils from former brown coal mines in a low-input, sustainable manner for biomass production. First, we conducted a survey of three former mining sites that vary in recovery time since mining (8, 12, and 18 years). From each site we performed a full soil analysis and analyzed plant biomass and species composition, mycorrhizal colonization, and microbial community structure, biomass, and activity. We found that soil abiotic parameters (pH, cation concentrations, extractable nutrients) did not change significantly between sites but that the youngest site had less microbial activity (extra-cellular enzyme activity) and less plant biomass, mostly due to lower herb, versus grass or legume, biomass. In addition we conducted greenhouse and field experiments to specifically test how different plant species grow with or without microbial inoculation (commercial AMF and N-fixing bacterial inocula, or 'native' inocula of undisturbed topsoil) on mineral sub-soil or mixed A and B horizon soil from an active mine. Initial results of these experiments suggest that both 'native' and commercial microbial inoculations can improve plant growth, but that this is highly plant-species dependent. In summary, specific microorganisms do play a role in the restoration of disturbed soils but this role may vary substantially based on specific plant species and localized site conditions.

S03.01-P -44

**THE ECOLOGICAL RECOVERY OF THE STERILE DUMPS FROM HUSNICIOARA QUARRY,
DISTRICT MEHEDINTI**

Dodocioiu Ana Maria*^[1], Mocanu Romulus^[1]

^[1]University of Craiova/Faculty of Agriculture and Horticulture ~ Soil Science and Plant nutrition ~ Craiova ~ Romania

In Romania the lignite coal is extracted by open cut mining. The open cut lignite mining determines the most harmful degradation of soil, the upper fertile layer of soil being replaced. In Oltenia, alone, by this kind of mining there are affected 17,400 ha. The ecological recovery of these lands is very important for locals and it assumes two main actions: - the reclamation, technical mining activity; - the biological recovery or ecological reclamation. In this respect, there were carried out researches on the gangues resulted after open cut mining in Husnicioara quarry – Mehedinti District that has affected 614 ha of which 329 ha of quarry and 285 ha as gangues. There were tried several crops on different doses of fertilizers and manure. The wheat crop does not succeed on gangues even with fertilization, the yields being of 448 – 1,208 kg/ha. The corn crop gives good yields on gangues only with manure and fertilizers; by chemical fertilization it can produce 2,200 kg/ha and by manure application, 3,500 kg/ha; The sunflower crop does succeed on gangues even without fertilization yet it can produce much better with mineral and organic fertilization. Pulses give good yields on gangues, the alpha-alpha crop has produced 4,417 kg of hay per hectare with organic and mineral fertilization. The same results are given by chickpea and peanuts. In order to fasten the versants of the gangue deposits, the best results were given by cross cropping of acacia

**THE EFFICIENCY OF DIFFERENT APPROACHES TO ANTI-EROSION PROTECTION IN
SELECTED AREAS**

Sarapatka Borivoj^{*,[2]}, Netopil Patrik^[1], Pavlik Frantisek^[3], Baran Jiri^[1]

^[1]Palacky University ~ Department of Ecology and Environmental Sciences ~ Olomouc ~ Czech Republic ^[2]Palacky University ~ Department of Ecology and Environmental Sciences ~ Olomouc ~ Czech Republic ^[3]Brno University of Technology ~ Department of Water Management ~ Brno ~ Czech Republic

Erosion is the most serious world-wide degradation factor and threatens the quality of soil and production of crops cultivated on it. Oldeman (1994) indicated that soil erosion accounted for 82 per cent of human-induced soil degradation, affecting 1,643 million hectares. Water erosion is also a serious problem in the Czech Republic (half of arable acreage). Recently, increasing numbers of farmers in Europe have been using agri-environment measures on the basis of Council Regulation 1257/1999. In 2002 roughly 25% of agricultural land in Europe was covered by agri-environment measures. Applicants for subsidies from these measures must also maintain Good Agricultural and Environmental Conditions (GAEC), which are based on Council Regulation (EC) 73/2009 and also cover erosion. A comparison of anti-erosion methods was carried out in chosen regions of Moravia in the Czech Republic. After evaluation of current potential erosion our research focused on comparison of GAEC anti-erosion efficiency and classically proposed anti-erosion protection (AEP) utilizing organizational, agro-technical and technical measures. The results indicate insufficient soil protection within GAEC management, especially in the area of Moravia. The efficiency of these measures in the analysed areas is between 13.6 % and 42.9 %. In comparison the efficiency of AEP, which unlike GAEC includes linear measures and soil-protective grassing in its conception, is within a range of 40.9 % to 73.4 %. With its rational utilization of landscape the AEP proposal fundamentally reduces soil loss due to water erosion and, in contrast to GAEC, uses an individual approach to the localities of interest.

THE EVALUATION OF EROSION HAZARD IN DASTKAN REGION - IRAN BY SLEMSA METHOD

Entazari Najafabadi Mojgan^[1], Rahimi Daryosh^[1], Shahzeidi Somayyeh Sadat^[1]

^[1]Isfahan University ~ Geography departmen ~ Isfahan ~ Iran, Islamic Republic of

In geographical studies, soil is not only considered as a natural resource, but also it is exposed to a corrupted danger called erosion, so it needs study, guarding and control. These quantities would be very useful for planning's. In this research, dominant erosion type, regions of more risks towards erosion rate and the most important influential in Dastkan auriferous basin which is located in north of Isfahan , between geographical length of 51°29'42" - 51°19' , 11" and geographical width of 33 °28'04" – 33 °38' , 02" were studied. To do this, data were gathered through library search, Aerial photograph of the region, , topographical and geology maps, GIS and RS techniques, Surfer 8 and ILWIS softwares. Also, basic maps for factors in SLEMSA model, such as isotherm, isorain, plant covering, geology and finally erosion rate maps were prepared. In the region, 5 erosion focuses in the north part were observed. Considering influential factors on these regions showed that the main erosion factor at the risk focuses was at first rain energy and the other factors were the ground gradient and plant covering .In addition, soil fatigue capability, which was the main erosion factor in the region, did not play so much role at the risk focuses .The research finding showed that water erosion is the dominant type of erosion in the region and erosion rate of average 1.412 ton per hectare is lower, compared to erosion rate of the country .

THE IMPACT OF ANTHROPOGENIC SOIL SEALING ON THE SOILS OF PROTECTED COASTAL LAGOONS (ALBUFERA DE VALENCIA, SPAIN)

Pascual Aguilar Juan Antonio*^[1], Andreu Vicente^[1]

^[1]Centro de Investigaciones sobre Desertificación (CIDE) ~ Degradación y Conservación de Suelos ~ Valencia ~ Spain

Anthropogenic soil sealing is one of the most worrying soil degradation factors to European level. Its development is a persistent threat in Mediterranean environments where socio-economic changes have produced the concentration of most productive activities in the alluvial coastal plains. Such trends may also affect soils in protected coastal lagoons. In this work a methodology based on the spatial and temporal analysis of artificial layers (concrete, asphalt, etc.) is developed. Data used have consisted in the extraction of soil sealing covers in polygon layers for the years 1991 and 2007, a layer with municipal limits and a layer with the limits of the protected area of the Albufera Natural Park, the study area located to the south of the city of Valencia, Spain. The analysis has consisted in the development of a set of statistics describing the situation of soil sealing and land fragmentation, understanding the first as the direct measure of soil losses and the later as a measure of loss of soils functionality. Results show that in 1991 almost 15% of the total administrative area studied was sealed and that it has increased to almost 19%, with variable trends according to individual municipalities. Such behaviour is identified in the soil of the protected area with smaller values, ranging from 3.75% in 1991 to 5.20% in 2007. The extension of the sealed surfaces has been also reflected in the fragmentation of soils with a considerable increase of soil patches and the subsequent reduction of their average size.

S03.01-P -48

THE QUALITATIVE EVALUATION OF SOIL EROSION HAZARD

Entezari Najafabadi Mojgan^{*[1]}, Gholami Majid^[1], Shahzeidi Somaieh^[1], Rashidi Masoumeh^[1]

^[1]univesity of Isfahan ~ Geography ~ Isfahan ~ Iran, Islamic Republic of

Soil erosion not only weakened soil, makes discouraging farms and a lot of hurt, but also causes destruction by sedimentation solid of materials in streams. Sources, dams, ports and decreases the amount of their capacity. One of the most central purposes in local studying and land use evaluation the hazard of erosion variation areas and determine its quantity. For evaluating erosion, there are many methods. In this methods, there are different factors such as rain erosion, value of erosion soil and plant coverage. In this study, we are studying soil erosion in Varmishgan basin between geographical length of 47° - 47°,38' and geographical width of 33 °,13' – 33 °,36' in Kohdasht in the northwest Lorestan province with SLEMSA method and using Arc GIS 9.3. SLEMSA is a model for estimation of soil erosion in southern Africa and developed and validated by Ewell(1978) and Stoking(1981,1988). For evaluating soil with this model, we obtained information maps contain topography, rainfall, slope and plant coverage. then with composing this layers, basin is separated to 100 units and the value of erosion soil is measured and giving value is as unit of erosive hazard in basin. . The results showed that the main erosion factor at the risk focuses was at first slope and the second factor was soil fatigue capability. The research finding showed erosion rate of average 667 ton per hectare

Key words: evaluation, soil erosion, Varmishgan

THE SOIL AND NUTRIENT LOSSES BY LIQUID RUNOFF ON SLOPE SOILS

Dodocioiu Ana Maria^{*[1]}, Mihai Susinsky^[1], Iulia Anton^[1], Tudosie Alexandru^[1]

^[1]University of Craiova ~ Soil Science and Plant Nutrition ~ Craiova ~ Romania

The paper presents the evolution of the response of soils and the main nutrients from hilly zones of Oltenia and Moldavia, respectively, Preajba and Perieni as well as their loss from the soil as a result of fertilization by several doses, ensuing the following: - the soils become more acid, especially due to unilateral fertilization with nitrogen; - the available phosphorus content decreases from the top of the slope toward the base where it increases as a result of fertile soil deposition; - the potassium is, also, taken by runoff and its content increases at the base of the slope; - the most eroded nutrient, both with slope soils surface and depth is nitrogen from applied fertilizers. Putting together the total nutrient losses there can be noticed that the nitrogen losses range between 0.66 and 81.93 kg/ha. The eroded potassium on slope plots is 0.15-12.82 kg/ha. The humus quantity taken away along with the eroded soil is between 10.38 and 1,439.40 kg/ha. The phosphorus records maximal values of 5.23 kg/ha, iron, 25-4,668 g/ha, manganese, 12-3,744 g/ha, copper, 0.63-112.81 g/ha and zinc, 1.5-957.1 g/ha. The maximal values of nutrient runoff on slope soils by liquid and solid losses are recorded with permanent furrow plots taken as control that are not protected against erosion at all. With the case of cropped plots, the highest losses were recorded with the not fertilized corn variant, the fertilization determining a higher resistance to erosion and nutrient losses. The lowest losses were recorded with the sown and fertilized pastures.

TREE COVER INFLUENCE ON WATER BALANCE OF SOILS IN SEMI-ARID REGIONS

De Boever Maarten*^[1], Cornelis Wim^[1], Gabriels Donald^[1]

^[1]Ghent University ~ Soil Management ~ Ghent ~ Belgium

*Several studies in arid and semi-arid regions have shown that isolated trees play an important role in reducing the negative effects of climate and soil aridity. They strongly influence the environments under their canopies by changing soil moisture, soil nutrients, microbial activity, light availability and temperature in these sites. The objective of this study was to investigate the impact of *Acacia raddiana* trees on soil hydraulic properties and the near-surface water content (0-10 cm). The study was conducted in an *Acacia raddiana* pseudo-savanna ecosystem in the Bou-Hedma National Park in central Tunisia. *Acacia* trees are considered as keystone species persisting spontaneous on the edge of the desert. Two sub-habitats were distinguished: tree-covered areas and open areas respectively located underneath and outside the canopy of *Acacia* trees. Samples were taken in each major wind direction at 0.5 m and 10 m from stem, respectively underneath and outside the canopy. Preliminary results show that the water-holding capacity of the near-surface soil underneath the canopy was significantly higher ($p < 0.05$) than outside the canopy (26.9 ± 4.0 vs. 21.6 ± 2.5 %). How this affects the soil water balance will be further investigated by measuring the evolution of near-surface soil water content in time for both sub-habitats after rainfall events during the wet season.*

A MATHEMATICAL MODELLING FOR LAND DEGRADATION IN A MINIATURE ARTIFICIAL RAIN MODEL

Almodaresi S.ali^[1]

^[1]yazd branch -islamic azad university ~ civil engineering department ~ Yazd ~ Iran, Islamic Republic of

The using mathematical methods have specific role in natural studies, whereas there isn't any other substitution among sciences. Earth changes problem is the best sample can make the usage of mathematical method applicable. wind, water and ice have the highest impact on morph changing of earth surface and make the biggest changes in passing of time. Despite we are speaking about astronomical time, But, since the time is a dynamic function, as it changes spatial changes will happen. The changes arise from environmental process in the time framework. Now, if we can design a model with mathematical methods that connect time and space -these two fundamental and important principals-in geomorphic changes .we will have a tool that can categorize the spatial periods with equal change means in evolution phases ,instead of dividing earth evolution periods base on time . this kind of modelling in earth science called ERGODISITY . Of course this concept has complex computational methods and relations in mathematics as Ergodic theorem. In this article we show with this method and with an artificial raining basin model we can state evolution phases base on space instead of time. after getting data from filed model we perform an virtual DEM by using Didger software and also we make interpolations by different methods in surfer software, then virtual Ergodic simulation made by Voxler software and the result confirmed as it mentioned above.

ABANDONMENT OF VINEYARDS AND ITS CONSEQUENCES IN ORGANIC CARBON, SOIL STRUCTURE AND WATER HOLDING CAPACITY

Acín Maria^[1], Marques Maria Jose^{*[2]}, Carral Pilar^[2], Alvarez Ana^[2], Gonzalez-Novoa Jose Antonio^[1], Lopez-De-Santiago Cesar^[1], Martin Berta^[1]

^[1]Universidad Autonoma de Madrid ~ Ecology Dept. ~ Madrid ~ Spain ^[2]Universidad Autonoma de Madrid ~ Geology and Geochemistry Dept. ~ Madrid ~ Spain

The study area (Cuenca, Spain) is located in a semiarid vast plain (2-8% slope, annual precipitation 500mm). The Calcisol (FAO) represents the dominant soil of this monotonous landscape of vineyards, few areas remain untouched by human activities. In recent years the abandonment of vineyards has been noticed. We study the characteristics of soils in active and abandoned (4 to 6 years) vineyards, and both are compared with a reference soil of *Quercus ilex* forests in the nearby study site. Soil organic carbon (OC), bulk density (BD), water-holding capacity (WHC), soil stability aggregates, hydraulic conductivity (Q) and number of fungal Colony-forming Units (CFU) as biodiversity indicator, were studied in topsoils. The reference soil yielded $5.2 \pm 2.2\%$ OC, $1.2 \pm 0.1 \text{ g.cm}^{-3}$ BD and up to $0.57 \text{ m}^3\text{m}^{-3}$ of water at field capacity. In contrast, active vineyards exhibited soils with $1.9 \pm 0.6\%$ of OC; $1.2 \pm 0.2 \text{ g.cm}^{-3}$ BD due to tillage, and $0.42 \pm 0.05 \text{ m}^3\text{m}^{-3}$ WHC. The abandoned vineyards experienced a slight increase in OC: $2.9 \pm 0.9\%$, a significant soil compaction: BD 1.6 ± 0.2 and less HWC: $0.41 \pm 0.1 \text{ m}^3\text{m}^{-3}$. The till management in vineyards increased the Q being four to five times higher than values found in forest and almost twice higher than values of abandoned vineyard. Nevertheless, that high Q was not complemented by better WHC. Consequently soil structure in vineyards was weaker, around 40 drops were needed to break soil aggregates in the reference soil, compared to 9 and 4 in abandoned and active vineyards. Soil biodiversity, significantly decreased from 5000 to less than 750 CFU in vineyards.

S03.02-P -3

AGRICULTURAL SOIL ALTERATION DUE TO LAND IMPROVEMENTS IN THE ALPS (AOSTA VALLEY, NW-ITALY)

Curtaz Fabienne^{*[1]}, Filippa Gianluca^[1], Freppaz Michele^[1], Galliani Cristina^[2], Zanini Ermanno^[3]

^[1]Università degli Studi di Torino ~ Di.Va.P.R.A. - Chimica Agraria e Pedologia - LNSA ~ Turin ~ Italy ^[2]Regione Autonoma Valle d'Aosta ~ Dipartimento Agricoltura-Assessorato Agricoltura e Risorse Naturali ~ Aosta ~ Italy ^[3]NatRisk ~ Di.Va.P.R.A. - Chimica Agraria e Pedologia - LNSA ~ Grugliasco-Turin ~ Italy ^[4]Regione Autonoma Valle d'Aosta ~ Dipartimento Agricoltura-Assessorato Agricoltura e Risorse Naturali ~ Aosta ~ Italy ^[5]Regione Autonoma Valle d'Aosta ~ Assessorato Agricoltura e Risorse Naturali ~ Aosta ~ Italy ^[6]Regione Autonoma Valle d'Aosta ~ Dipartimento Agricoltura-Assessorato Agricoltura e Risorse Naturali ~ Aosta ~ Italy

Land transformations in the mountain regions generally produce impact on soil chemical, physical and biological properties. Land improvements are often carried out to allow farmers to easily cultivate and increase the mechanizable soils. However, the effects on soils of some common practices like rock removals, levelling and milling are frequently unknown. The aims of this study are: 1) the assessment of impacts of land improvements on soil properties and 2) the detection of the best pedotechniques and practices of restoration. We investigated 3 study areas in the Aosta Valley Region (NW Italy). Soil sampling was carried out in sectors of different age and in a control, where the land improvements were not conducted. Additionally, we evaluated the effect of different organic fertilizers (i.e compost and organic manure) on soil quality during the restoration processes. All soil samples have been analyzed for chemical and physical properties. Specific analyses included water aggregate stability (WAS) and Atterberg limits. Recent improvements (2008) generally resulted in a turbated soil organic carbon profile, with higher values at greater depth than in surface. The land improvements caused a general decrease of the soil organic matter content in comparison with the control, and show a higher susceptibility to erosion. The soils before the amelioration practices could be extremely stony and consequently the use of an allocthonous soil could be necessary. Since these important effects of land improvements on the soil characteristics, the definition of best practices is essential in order to reduce impact, costs and ensure better results.

S03.02-P -4

ASSESSING THE SOIL EROSION RATE OF SLOPING VINEYARDS BY MEANS OF MODIFIED MMF-SAGA MODEL

Biddoccu Marcella^{*[1]}, Cavallo Eugenio^[1], Setiawan Muhammad Anggri^[2], Wichmann Volker^[3]

^[1]Italian National Research Council ~ Institute for Agricultural and Earthmoving Machines - IMAMOTER ~ Turin ~ Italy

^[2]University of Gadjah Mada ~ Department of Geography and Environmental Science ~ Jakarta ~ Indonesia ^[3]alpS ~ Center for Climate Change Adaption Technologies ~ Innsbruck ~ Austria

The IMAMOTER-CNR monitored a 10-years period of soil erosion in vineyards of the Piedmont Experimental Vine and Wine Centre, in the Alto Monferrato area (NW Italy). To support and continue the monitoring period, this study applies a spatially-distributed soil erosion model in three vineyard areas characterized by different inter-rows practices, i.e. controlled grass cover (GC), conventional tillage (CT) and reduced tillage (RT). For that purpose, we implemented the Modified MMF model as module for the FOSS GIS SAGA. In order to improve model performance, our implementation of this model includes i) the use of a channel network layer, by which the sediment and runoff are concentrated, ii) the use of a multiple flow direction algorithm for sediment and runoff routing, and iii) a time-span parameter which indicates the number of simulation days. In total, 63 runoff and sediment measurements of single or accumulative rainfall events were used during model evaluation. After preprocessing the input data, the model was calibrated separately for spring, summer and autumn season based on the channel network density which in fact follows the tractor paths. Evaluation of model performance was carried out by using the effectiveness coefficient introduced by Nearing. The results show that the differences between measured and predicted soil erosion are in an acceptable range and imply that the Modified MMF model is not only effective as a monitoring tool but can also be used for simulating different conservation scenarios in order to reduce the soil erosion problem in vineyards.

S03.02-P -5

ASSESSMENT OF PHOSPHORUS TRANSFER FROM AGRICULTURAL LANDS TO THE SURFACE WATER IN FRANCE

Delmas Magalie^{*[1]}, Arrouays Dominique^[1], Cerdan Olivier^[2], Gascuel-Odoux Chantal^[3], Mouchel Jean-Marie^[4]

^[1]INRA ~ INFOSOL ~ Orléans ~ France ^[2]BRGM, French Geological Survey ~ RIS ~ Orléans ~ France ^[3]INRA ~ Soil Agro and hydroSystem ~ Rennes ~ France ^[4]University Paris 6 ~ UMR Sisyphe ~ Paris ~ France

Diffuse phosphorus (P) transfer from agricultural lands to surface water contributes to eutrophication. It has increased attention in the last decades, notably due to a real improvement of water treatment from urban areas which induce a higher relative part of agricultural sources. Methodologies are required for water quality assessments at large scale as a part of the implementation of the EU Water Framework Directive. In this context, a methodology is presented which aims to investigate what is the fraction of hillslope P production which reaches the river systems, and finally, to better identify the origin of P observed in rivers. The proposed model combines mobilisation and transfer processes: P and soil particles are firstly mobilised by water erosion, and then they are delivered via surface and sub-surface flow pathways to the river network. The method takes into account the spatial distribution of major properties that control the mobilisation of P by soil erosion and its transfer to the water bodies. Description of P transfer is based on the establishment of connectivity indicators which describe hillslope flow pathways, potential retention, attempting to link basin characteristics to a prediction of phosphorus exports in rivers. The model is calibrated and validated with phosphorus fluxes calculated in French rivers. This study provides insight in the identification of the most influent soil particles and P redistribution processes on the total P fluxes, and the difference between various types of basins.

S03.02-P -6

ASSESSMENT OF THE EROSION RISK IN THE FEDERAL STATE OF BRANDENBURG IN THE CONTEXT OF CROSS COMPLIANCE

Deumlich Detlef*^[1], Roger Funk^[1]

^[1]Leibniz-Center for Agricultural Landscape Research (ZALF) ~ Institute for Soil Landscape Research ~ Müncheberg ~ Germany

Cross-compliance (CC) is a policy tool that attaches conditions to the receipt of agricultural subsidies/direct payments. Since 2005 all farmers receiving direct payments and managing field blocks with a water or wind erosion risk are subject to restrictions and/or specific soil protection measures. Basis of a comparable and fair risk assessment are consistent data of the main controlling factors with a high spatial resolution. The water erosion risk is estimated with a German adaption of the (R)USLE using soil and topography data in a 25m-grid. The wind erosion risk is derived from soil and wind data considering the sheltering effects of landscape structure in a 10m-grid. Unfortunately, the high spatial resolved assessment with all risk classes is averaged by the weighted mean for a field block, considering only the percentage of the highest risk classes. The real erosion risk is underestimated by this procedure. Discrepancies exist between the minimum standards for CC and effective soil protection resulting in intense discussions between different interests. More suitable is a comparative method (SICOM) to evaluate complex site conditions at different area units as a basis for the estimate of spatial equivalence. Objects with heterogeneous contents can be aggregated to comparison groups and sorted by index, indicators, triple or others. The information can assist the soil protection policy of the EU to achieve the right balance between competitive agricultural production and the respect of nature and environment. The methods are introduced, compared and discussed in its consequences for soil protection.

BREAKDOWN OF SOIL AGGREGATES DEVELOPED ON DIFFERENT PARENT MATERIAL USING LOW INTENSITY ULTRASONIC VIBRATIONS

Lehtinen Taru*^[1], Lair Georg J.^[1], Mentler Axel^[1], Blum Winfried E.h.^[1]

^[1]University of Natural Resources and Life Sciences (BOKU) ~ Institute of Soil Research ~ Vienna ~ Austria

Ultrasonic dispersion of soil aggregates is widely used, since it involves no chemical agents and enables further soil characterization such as quantification and characterization of occluded particulate organic matter (POM). However, currently available equipment is difficult to use at very low ultrasonic energy levels. Therefore, Schomakers et al. (2011) recently developed an ultrasonic device for low energy soil applications. The aim of this study is to link the soil aggregate breakdown with physicochemical soil properties, in order to calibrate energy levels that can be applied in different soils while maintaining e.g. microaggregates. Surface soils (0-20 cm) developed on different parent materials (alluvial sediments, volcanic material, serpentinite, limestone, granite) were collected and dry-sieved for 250-1000 μ m-sized aggregates. The study focused on how i) soil organic matter (SOM), ii) iron oxides and iii) clay content affects the breakdown of the aggregates as well as on iv) the characterization of SOM in the studied aggregates. With the new ultrasonic dispersion equipment low energy levels were used in six steps (2-40 J ml⁻¹). Dissolved organic carbon (DOC) was gained by UV absorption at 254nm and Simultaneous Thermal Analysis (STA) was used to characterize SOM. The study showed that breakdown of the aggregates at low energy levels (2 J ml⁻¹) was fastest in soils on alluvial sediments, followed by soils on volcanic material, serpentinite, limestone and granite. These results show that low ultrasonic dispersion is a very successful tool to follow soil aggregate breakdown but it needs to be adjusted to soils on various parent materials.

CARBON LOSSES AND AGROECOLOGICAL ASSESSMENT OF ERODED SOILS UNDER DIFFERENT BIOCLIMATIC ZONES OF RUSSIAN PLANE

Zinaida Artemyeva*^[1]

^[1]Moscow Timiryazev Agricultural Academy ~ Faculty of Soil Science, Agrochemistry and Ecology ~ Moscow ~ Russian Federation

The regularities of organic-mineral profiles formation of eroded Luvisols, Greyzems and Chernozems under different bioclimatic zones of Russian plane were investigated. A number of in humic changes and aggregate content of arable soils under the erosion have been established: the reduced content of CLF and the portion in total Carbon are accompanied by increase of the portion of CCl and it's accompanied by reduction of the ratio of Carbon in light (CLF) and clay (CCl) fractions (CLF/CCl) up to the observed minimum amount, and the quantity of ratio between the Carbon, accumulated in coarse (50-250 μm) and fine (1-50 μm) microparticles (Ccr/Cfn), which change in direction of increase markedly of Ccr. The low CLF/CCl – one of the basic reasons of upper horizon's bulk density increase (on average of $11\pm3\%$). Unfavorable properties of eroded soils are determined their low crop-producing power (~20% of non-eroded soils). The participation of accumulative processes in formation of eroded soils smooth out the negative influence of erosion, partially, and forward the bulk density reduction of soils in zone of prevail sediment accumulation and increase crop-producing power (~30% of eroded soils). The C losses of various organo-mineral fractions of eroded soils from different bioclimatic zones of Russian plane have been estimated. For the first time the system of eroded soils markers has been suggested. The scale of agroecological assessment of zonal eroded soils of Russian plane has been devised. In the base of scale are underlying 5 indexes. The quantitative indices CLF/CCl and Ccr/Cfn are among them.

**CHANGES IN SOIL CARBON AMOUNTS UNDER THE IMPACT OF RAPID GROWTH
URBANIZATION IN NORTHERN IRAN**

Khaledian Yones^[1], Kiani Farshad*^[1], Ebrahimi Sohaila^[1]

^[1]Gorgan university of agricultural sciences and natural resources ~ soil science ~ Gorgan ~ Iran, Islamic Republic of

Urbanization is the most drastic form of land use change affecting ecology and ecosystem functioning and services far beyond the limits of cities. To understand the process of urbanization itself as well as its ecological consequences, it is important to quantify the temporal patterns of urbanization. We characterize the effects of temporal patterns of Ziarat village – the tourism region in the Golestan province – using evaluation of land use changes in four land use; forest, pasture, cultivated and urban on changes of soil carbon including total carbon, labile, non-labile carbon, mineral carbon and their relationships by bulk density parameter. The results showed that percent carbon means were 4.94, 3.01, 2.1, and 1.42 in the forest, pasture, cultivated and urban respectively. This parameter was decreased by 39, 56 and 71 % respectively in comparison with the forest. furthermore, Labile carbons decreased in urban, cultivated and pasture land uses by 87, 66 and 54 % respectively and also non-labile carbons decreased in urban, cultivated and pasture by 76, 49 and 34 % respectively. The Bulk density had been increased in cultivated, pasture and urban in comparison with forest. The mineral carbon was increased in urban, cultivated and pasture in comparison with forest. Because Ziarat watershed is the most important drinking water source of Gorgan (the capital of Golestan province), this study demonstrated that trend of soil degradation, carbon emissions and mismanagement caused increasing hazard of urban floods, sediment problem and human health problems in main city of province.

CHANGES OF BULK DENSITY AND AIR-WATER PROPERTIES OF SOILS IN BASINS WITHOUT OUTLETS AS AN EFFECT OF EROSION AND ANTHROPOGENIC DENUDATION, STUDIES FROM NORTH-WESTERN POLAND

Przewozna Bogusława*^[1]

^[1]Institute of Geography and Spatial Organization ~ Polish Academy of Sciences ~ Warsaw ~ Poland

The aim of the study was to investigate changes of physical soil properties caused by natural erosional and depositional processes and anthropogenic activity in basins without outlets in young glacial landscape (north-western Poland). The research was conducted in two toposequences connected with different types of land use (crop field, grassland). Sedimentary basins have been an object of interest for geomorphology, hydrology and pedology. Soil erosion research in basins without outlets in Poland are rare. These objects are those areas which have taken place the constant depositional and erosional processes in. As an effect of natural and anthropogenic denudation processes, soils located in the bottoms of the sedimentary basins are subjected to compression and thus to changes in soil porosity, bulk density and also morphology. Intensity of this occurrence depends on slope length and degree, properties of soil (texture, clay and organic matter content, structure, permeability, drainage), climate (especially rainfall), type of land use, etc. This research are supported by Polish Ministry of Science and Higher Education (research project no. N N305 056240).

CONDITIONS FOR THE OCCURRENCE OF SLAKING AND OTHER DISAGGREGATION PROCESSES UNDER RAINFALL

Dalla Rosa Jaqueline^[1], Cooper Miguel^[1], Darboux Frédéric^{*[3]}

^[1]Escola Superior de Agricultura "Luiz de Queiroz", Universidade de São Paulo ~ Soil Science Department ~ Piracicaba ~ Brazil ^[2]Institut National de la Recherche Agronomique ~ UR 0272 - Soils ~ Orléans ~ France ^[3]Institut National de la Recherche Agronomique ~ UR0272 Soils ~ Orléans ~ France

Aggregation is a major feature of soil structure. It affects transfer of water and gas through the soil and at the soil surface, plant growth, etc. Under rainfall, seedbed structure evolves, leading to crust development, which affects overland flow and erosion. This evolution depends on both rainfall properties (intensity, drop size distribution, initial wetness) and soil properties (aggregate size distribution, stability). Four major disaggregation processes have been identified : (1) slaking due to air entrapment, (2) micro-cracking due to differential clay swelling, (3) mechanical breakdown due to kinetic energy and (4) clay dispersion. Clay dispersion occurs under sodic conditions. It was previously shown that mechanical breakdown and micro-cracking can actually take place under rainfall. However, slaking has only been demonstrated for aggregate stability tests. To test the occurrence of slaking under rainfall, a experiment was conducted under controlled conditions. It used the rainfall simulation facility of the soil science laboratory (INRA, Orléans. France). Two soils with different textures (a clay loam and a silt loam) were used because of their known difference in sensitivity to slaking, as shown by aggregate stability tests. Initially dry aggregates (1-3 mm and 3-5 mm size ranges) were placed under rainfall (deionized water) for various durations, allowing the measurement of disaggregation through time using a laser diffraction sizer. Four rains with different kinetic energy and rainfall intensity were used. Results allow to distinguish between disaggregation processes and to specifically identify slaking. Using complementary studies from the literature, their conditions of occurrence under rainfall are outlined.

DECENTRALISED POLICY FOR SUSTAINABLE WETLAND RESOURCES IN THE IGULUIBI AND UPPER RIVER RUIZI WATER CATCHMENTS LAKE VICTORIA BASIN UGANDA.

Nakiyemba Were Alice*^[1], Isabirye Moses^[1], Mathijs Erik^[2], Deckers Seppe^[3], Poesen Jean^[3], Maertens Miet^[3]

^[1]Busitema University ~ Natural Resource Economics ~ Tororo ~ Uganda ^[2]Catholic University of Leuven, ~ Earth and environmental Sciences ~ Leuven ~ Belgium ^[3]Catholic University of Leuven, ~ Earth and environmental Sciences ~ Leuven ~ Belgium

This study was conducted within the framework of the VLIR-OI project with the aim of making contributions to the Diagnosis and Remediation of Land Degradation Processes in the Riparian Zone of Lake Victoria Uganda in view of reducing sediment pollution of the Lake Waters. The conservation and management of wetlands in Uganda is devolved from the central to the local level, which shifts the main responsibility for wetlands to the local governments. Decentralisation of natural resource management is said to have some considerable benefits for a more sustainable management of the natural resource, but it also has some drawbacks that can hinder successful management. Despite the importance of wetlands for Uganda, they are seriously degrading due to converting them into agricultural farm land. The study seeks to investigate whether or not decentralised governance is beneficial for sustainable wetland management and in which way wetland management can be improved from a stakeholders' perspective in light of the current farming systems and practices and their contributions to land degradation and pollution of the Lake Victoria waters in Uganda. The study used a mixed methods approach that is, qualitative and quantitative and is based on the Institutional theory. Findings revealed lack of coordination, lack of awareness about the decentralised policy by the farmers, lack of enforcement mechanisms and political interference and among the challenges the policy is facing.

S03.02-P -13

EFFECT OF PERSISTENT SUBSOIL COMPACTION ON N₂O EMISSIONS FROM ARABLE SOILS

Simojoki Asko^{*[1]}, Regina Kristiina^[2], Alakukku Laura^[3], Thomas Keller^[4], Hanna Silvennoinen^[5], Dörsch Peter^[5]

^[1]University of Helsinki ~ Department of Food and Environmental Sciences ~ Helsinki ~ Finland ^[2]MTT Agrifood Research Finland ~ Plant Production ~ Jokioinen ~ Finland ^[3]University of Helsinki ~ Department of Agricultural Sciences ~ Helsinki ~ Finland ^[4]Agroscope Research Station ~ Soil Fertility and Soil Protection Group ~ Zurich ~ Switzerland ^[5]Norwegian University of Life Sciences ~ Department of Plant and Environmental Sciences ~ Ås ~ Norway

Fluxes of nitrous oxide (N₂O) and soil air composition were studied in two field experiments in southern Finland and Sweden, where persistent compaction effects by the heavy wheeling of a clay soil and a sandy clay loam soil in 1981 (Finland) and 1995 (Sweden), were still found in the subsoil. Samples of N₂O emissions and soil air were taken biweekly in 2009-10 both with chambers on the soil surface and gas samplers in the soil profile and analysed by gas chromatography. The annual fluxes of N₂O (mean \pm standard deviation) during Oct 2009 - Sep 2010 in the control and compacted treatments, respectively, were 8.6 ± 3.7 and 9.4 ± 1.0 kg N ha⁻¹ in Finland, and 10.0 ± 4.1 and 8.3 ± 3.8 kg N ha⁻¹ in Sweden, with no significant differences between the treatments. The concentrations of N₂O at the depths of 15, 30, 50 and 70 cm correlated positively with the emission of N₂O from the soil in both fields ($r = 0.4-0.7^{***}$). Compaction tended to increase N₂O in soil air. The oxygen concentrations in the subsoil correlated negatively with the N₂O emission, but only at the Finnish site. The results suggest that despite periods of impaired subsoil aeration and higher concentrations of N₂O in soil air, subsoil compaction does not significantly increase N₂O emissions from these soils to the atmosphere 15-30 years after compaction. This may indicate a minor role of subsoil in the production of N₂O compared with topsoil.

S03.02-P -14

EFFECTS OF EROSION ON GREENHOUSE GAS FLUXES IN A YOUNG MORAINELANDSCAPE OF NE GERMANY

Pohl Madlen*^[1], Ulrike Hagemann^[1], Mario Liebe^[1], Denise Dey^[1], Michael Sommer^[1], Jürgen Augustin^[1]

^[1]Leibniz-Centre of Agricultural Landscape Research (ZALF) e.V. ~ Institute for Landscape Matter Dynamics ~ Müncheberg ~ Germany

Little is known about the management-induced erosion on the greenhouse gas (GHG) exchange and carbon (C) budget of arable sites in glacially shaped young moraine landscapes. In an interdisciplinary approach, the CarboZALF-D project investigates the impact of various factors such as erosion on GHG fluxes and C dynamics of such a landscape in NE Germany. We present GHG and C dynamics of maize based on 2-years of measured and modeled fluxes of four erosion-related soil types: a) non-eroded luvisol, b) eroded luvisol, c) pararendzina and d) colluvisol. CO₂ measurements were conducted every four weeks using a non-flow-through non-steady-state closed chamber system (Livingston and Hutchinson 1995) based on Drösler (2005). Measurement gaps were filled by modeling CO₂ fluxes using the Lloyd-Taylor (Lloyd and Taylor 1994) and Michaelis-Menten (Michaelis and Menten 1913) modeling approaches. N₂O and CH₄ were measured bi-weekly using a static chamber system with interval sampling. Results show that soil type (erosion/ deposition) and weather conditions have a strong influence on GHG exchange. Deposition induces increased N₂O emissions and CH₄ uptake. In contrast, erosion clearly decreases ecosystem respiration, gross primary production and C export (harvest). Due to the opposing direction of these fluxes, however, differences between the overall annual C balance of eroded and non-eroded sites are relatively small.

EVALUATING THE IMPACT OF HYDROFOBICITY IN OLIVE GROVES OF SOUTHERN SPAIN

Burguet Maria^{*[1]}, Taguas Encarnacion V.^[2], Cerda Artemio^[3], Gomez Jose Alfonso^[1]

^[1]Institute for Sustainable Agriculture (IAS), Cordoba, Spain ^[2]University of Córdoba, Department of Rural Engineering, Cordoba, Spain ^[3]University of Valencia, Soil Erosion and Degradation Research Group. Department of Geography, Valencia, Spain

The effects of hydrofobicity in olive groves were studied in three different olive orchards in Cordoba (Southern Spain), under different soil types (Vertic and Frank). The initial hypothesis is that hydrofobicity exists in olive crops, but it might not be a significant issue for the global hydrological cycle. This study presents the first results of hydrofobicity measurements in the hydrological year of 2011-2012. Samples of topsoil humidity were collected during the dry period, and soil hydrofobicity was measured following the Water Drop Penetration Time method. This was done within a 1 m transect, taking the olive trunk as its centre. Two distinct zones were considered for the measurements: beneath the tree as well as the open rows between trees. Hydrofobicity was found in two of the three sites although the values were not high –the maximum WDPT was 27 minutes-. More research needs to be done in order to complete de measurements under different soil moisture and organic matter conditions.

EVALUATION OF SOIL PHYSICAL QUALITY UNDER DIFFERENT SOIL LAND USES IN A SMALL SICILIAN WATERSHED

Bagarello Vincenzo^[1], Castellini Mirko^[2], Iovino Massimo^{*[1]}

^[1]Univ. di Palermo ~ Dip. Sistemi Agro-Ambientali ~ Palermo ~ Italy ^[2]CRA ~ SCA ~ Bari ~ Italy

Sustainability of extensive rain fed agriculture needs assessment of land use effects on soil physical and hydraulic properties. Several soil physical quality indices were determined for four adjacent areas in a small Sicilian watershed, that were characterized by a different land use, namely cropland (C), olive grove (O), grassland (G) and eucalyptus plantation (E). Soil texture was similar for the considered areas, even if the no-tilled soils (G and E) showed a higher clay content in the top layer (0-20 cm) than in the lower layer (20-40 cm). The bulk density of the top layer ranged between 1.20-1.43 g cm⁻³ (C < G < O < E), with significant differences between C and E. In the lower layer, it ranged between 1.16-1.43 g cm⁻³ (C < O < E < G), with bulk density of C that was significantly smaller than that of the other land uses. The organic matter content was generally low and comparable for the different areas (in average 1.6%). The near-saturated soil hydraulic conductivity values were significantly higher for no-tilled (G, E) than tilled soils (C, O), whereas the opposite result was found for smaller degrees of saturation. The Dexter's soil quality index assumed similar values in both the top (0.024-0.047) and the lower layer (0.024-0.040), with the higher values associated to tilled soils. According to existing guidelines, the soil physical quality of the selected areas was generally poor independently of the land use. However, the cropland showed a better quality than the other land uses.

FROM A GEOCHEMICALLY TO A PHYSICALLY-DRIVEN SOIL BLEACHING: THE ROLE OF AGRICULTURAL PRACTICES

Montagne David*^[1], Sophie Cornu^[2], Isabelle Cousin^[3]

^[1]UMR INRA/AgroParisTech EGC ~ Soil Science ~ Paris ~ France ^[2]INRA GSE ~ geochemistry ~ Aix-en-Provence ~ France ^[3]INRA Sciences du sol ~ Soil Science ~ Orléans ~ France

To model soil evolution at the century scale, it is necessary to take into account changes in the direction and/or the velocity of pedogenic processes as a result of a change in land use and of agricultural practices. Albic horizons are one of the most widespread soil features and their genesis found to be particularly sensitive to changes in environmental conditions related to agricultural practices. However, the precise genetic pathways involved in the genesis of albic horizons and the impact of agricultural practices on the intensity of this process remained controversial. The intensity of soil bleaching in the E&Bt-horizon of Albeluvisols was quantified using a combination of image analysis and mass balance calculations along an anthropo-chrono-sequence consisting in i) a forested soil, ii) a limed and amended with organic matter cultivated soil unaffected by agricultural drainage improvement, and iii) the same soil affected by drainage. We showed that liming slows down the velocity of soil bleaching and agricultural drainage increases its velocity demonstrating that several agricultural practices might have contrasted impacts. Moreover, soil bleaching is driven by redox processes under forest, but mostly by physical translocation of fine soils particles in the drained soil. This last result demonstrates that several genetic pathways might produce similar soil features. Modelling soil evolution requires thus to model simultaneously several processes whose relative intensity and velocity vary according to small changes in environmental conditions as those resulting for example from various agricultural practices.

GEOMETRY OF SOIL AGGREGATION

Parent Léon E.*^[1], Serge-Étienne Parent^[1]

^[1]Université Laval ~ Soils and Agrifood Engineering ~ Quebec ~ Canada

Soil aggregation is a sensitive indicator of soil structure. Soil aggregates are made of closely packed sand, silt, clay, and organic particles. They vary in size from nanoparticles of organo-mineral complexes to large peds. Aggregate-size distribution is measured by sieving under mechanical stress. Mean weight diameter (MWD), developed in 1949, is the usual synthetic measure of soil aggregation. However, MWD is inherently biased and non Euclidean. MWD is scale-dependent and conveys redundant information (one proportion, computed by difference between 100% and the sum of other proportions, can be omitted) that lead to spurious correlations and distort multivariate analysis. The isometric log ratio (ilr) transformation is an unbiased alternative developed by compositional data analysts in 2003. Ilr is based on mass balances of aggregate-size subcompositions orthogonally arranged to portray soil aggregate build-up. Each ilr is a coordinate in the Euclidean space and thus provides geometry to soil aggregation. The Aitchison distance between two compositional vectors x and y ($A(x,y)$) is a synthetic measure of soil aggregation computed across ilr coordinates. Our objective was to relate MWD to $A(x,y)$ distances between two compositions using two published studies on Brazilian soils. The correlation between MWD and $A(x,y)$ is a measure of the bias inherent to MWD since ilr is scale-invariant and free from spurious correlations. Correlation coefficients were 0.99 for the Oxisol but 0.77 for the Alfisol. We suggest discontinuing MWD and to use ilr and the Aitchison distance as measures of soil aggregation. The ilr concept may allow comparisons between studies.

S03.02-P -19

GULLY EROSION PREDICTION IN A SAHELIAN CONTEXT

Gay Aurore^[1], Olivier Cerdan^[1], Jean-François Desprats^[2], Oumarou Malam Issa^[3], Christian Valentin^[4], Jean-Louis Rajot^[5], Luc Descroix^[6]

^[1]BRGM ~ RIS ~ Orléans ~ France ^[2]BRGM ~ RIS ~ Montpellier ~ France ^[3]IRD ~ BIOEMCO ~ Niamey ~ Niger ^[4]IRD ~ BIOEMCO ~ Bondy ~ France ^[5]IRD ~ BIOEMCO ~ Créteil ~ France ^[6]IRD ~ LTHE ~ Grenoble ~ France

In Sahelian region, concentrated overland flow often leads to the formation of gullies. Although this phenomenon is widespread in those regions, research efforts are still needed to be able to model their spatial distribution and the role of the different parameters involved in this process. In this context, the objectives of this study are twofold. The first step is to investigate to what extent the role of Sahelian soil surface crusts (biological and/or physical) on soil surface infiltrability and detachment affect the formation and development of gullies. The second step is to integrate the results of these investigations in a simple geomorphological model to predict gully location at the watershed scale. The evaluation of the resulting model on two test catchments demonstrated that the integration of soil crusting is a key parameter to insure the quality and relevance of gully prediction. The model is able to distinguish between two types of gullies, those whose width range between 0.5m and 4m and those whose width exceeds 4m. The application of the model at the regional scale is however limited by the resolution of available regional digital elevation model (i.e. the 90m resolution SRTM DEM) which only permits the prediction of large gullies. Key words: erosion, gullies, Sahel, biological soil crusts, modelling.

HIGH SCALE EROSION MODELLING FOR MUDDY FLOOD INVESTIGATION

Arévalo Sarah Annika*^[1], Schmidt Jürgen^[1]

^[1]TU Bergakademie Freiberg ~ Soil and water conservation ~ Freiberg ~ Germany

The flooding of streets and properties by runoff from agricultural land carrying large quantities of sediment, does not only represent an annoyance for the residents (gardens and cellars flooded with mud, impassable street, etc.) but also produces significant cleaning up cost. In the case of heavy rainfall events the occurrence of such muddy floods depends on the one hand on the susceptibility of the adjacent agricultural land to soil erosion, especially during unprotected states in the agricultural year. On the other hand the structure of the settlement area, the characteristics of streets, pavements, ditches, etc. strongly influence the conduction of runoff and hence sediment-deposition areas. In order to implement effective protection measures for areas threatened by muddy floods it is essential to predict the produced runoff during single extreme rain events, the amount of detached soil, and the areas where the runoff and sediment load is transported to. In the presented study a method is developed to implement anthropogenic constructions to surface data and to use this information for the modeling with the process-based soil erosion model EROSION 3D. The results show that with this method it is possible to model a real case of muddy flood as well as to validate on- and off-site protection measures.

HIGH-RESOLUTION EROSION RISK MAP OF SWITZERLAND IN A 2X2-METER GRID (ERM2)

Prasuhn Volker*^[1]

^[1]Research Station Agroscope Reckenholz-Tänikon ART ~ Natural Resources and Agriculture ~ Zurich ~ Switzerland

The high-resolution erosion risk map (ERM2) of Switzerland's utilised agricultural area is based on an modified version of the Revised Universal Soil Loss Equation (RUSLE) using multi-flow algorithm. It shows potential erosion risk based on the locational factors of relief, soil and precipitation – irrespective of particular land use (arable land, permanent grassland or vines) or crop management. Areas at high risk of erosion within a field or on a hillside, such as talwegs for example, are easy to identify on the map. Erosion damage mapping in the field, comparisons with other erosion risk maps and discussions with farmers have confirmed the validity of the map. Altogether, 44 % of the utilised agricultural area in the valley and hilly region was classified as a potential erosion risk on the basis of a 2x2-meter grid. 38 % of all the land in the valley and hilly region is used as permanent grassland, however, and to this extent poses no real erosion risk. A digital map of arable land is not currently available, so the land could not be broken down into arable and permanent grassland. ERM2 now provides a standard basis for assessing the potential erosion risk on field scale for the whole agricultural area of Switzerland. It enables farmers and cantonal advisors to identify in advance the land at risk of potential erosion, assess it jointly in situ and plan the requisite action. It remains essential, however, to carry out a field inspection of the erosion risk modelled.

**IMPACT OF RAPID URBANIZATION ON SOIL DEGRADATION IN ZIARAT WATERSHED
GOLESTAN PROVINCE, NORTH OF IRAN**

Khaledian Yones^[1], Kiani Farshad*^[1], Ebrahimi Sohaila^[1]

^[1]Gorgan university of agricultural sciences and natural resources ~ soil science ~ Gorgan ~ Iran, Islamic Republic of

This paper introduces a dynamic systems based method for assessing the impacts of urbanization policy on land use change with reference to the urbanization practice in Ziarat, Golestan province. In this study, the mean weight diameter (MWD), bulk density, soil porosity, density of soil, Soil infiltration rate, organic carbon and calcium carbonate equivalent soil upper layers (0–30 cm) and analysis of them were taken by completely randomized split-plot in the three land uses forest, cultivated and urban in Ziarat watershed and with two the north and west aspect geography, and five replication designed. The results showed that under natural conditions the contents of were largest in the forest, moderate in cultivated and smallest in the villa building area. MWD contents in different land uses intensive decreased in the order of urbanization, deforestation and changed land use. Bulk density of surface soil samples showed that this parameter increased in two land uses cultivated and urban. The soil porosity decreased in urban increased in cultivated land use that was due to tillage. Soil density was signification differences between forest and both lands use cultivated and urban areas. Soil infiltration rate in urban land use was the less than of all lands use that it has been showing intensive degraded soil. Therefore, it is important to recognize the possibility of future contaminant because Ziarat watershed is above Gorgan, this study demonstrated that trend of degradation and mismanagement increase hazard of urban floods and human health.

S03.02-P -23

IMPACT OF TILLAGE ALONG A SOIL TOPOSEQUENCE IN A TRADITIONAL CEREAL CROP

Bienes Ramon^[1], Marques Maria Jose^{*[2]}, Ruiz-Colmenero Marta^[3], Alvarez Ana^[2], Jimenez-Ballesta Raimundo^[2]

^[1]Universidad de Alcala ~ Geology Department ~ Alcalá de Henares ~ Spain ^[2]Universidad Autonoma de Madrid ~ Geology and Geochemistry Dept. ~ Madrid ~ Spain ^[3]IMIDRA, Consejería Medio Ambiente ~ Environmental Dept. ~ Alcala de Henares ~ Spain

We investigated the long term impact of tillage in the topsoil of a cereal cultivated slope in Castile (Spain) using two toposequences of ~500 m. These were characterised by a reference site of Quercus sp. forest at the top of the toposequences, followed by homogeneous agriculture soil use along variable slopes (16 ± 12 %) which ended in a flat valley. The variations in soil organic matter (OM), texture, electrical conductivity (EC), and pH were studied. Results yielded differences in OM between the reference topsoil, 3.6 %, and soil samples from the slope close to the valley, 0.7%. Clay fraction increased from 8% found in the reference site, to 19% in the valley, where the illite mineralogy of clays was predominant; pH increased from 6.5 to 7.7 progressively down the slope due to high content of CaCO₃; and EC also increased from 0.6 to 0.9 dS m⁻¹. On the contrary the stability of aggregates in soil samples decreased in the slope up to 90%. Strong correlations between the activity of ¹³⁷Cs and clay content were realized. Higher radioactivity emissions ranging from 2.2 Bq kg⁻¹ to 35.6 Bq kg⁻¹ were found in the forest topsoil, compared to lower values detected along the slope. The activity of ¹³⁷Cs was used to estimate soil loss, using an exponential model. High erosion rates were obtained for both toposequences, 27 ± 14 and 29 ± 7 Mg ha⁻¹ year⁻¹, representing annual erosion rates since the initiation of till agriculture management in the slopes.

INVESTIGATING SYNDROMES OF AGRICULTURAL LAND DEGRADATION THROUGH PAST TRAJECTORIES AND FUTURE SCENARIOS

Salvati Luca^{*[2]}, Bajocco Sofia^[1], Rinaldo Simone^[1], De Angelis Antonella^[1], Perini Luigi^[1], Ceccarelli Tomaso^[1]

^[1]Consiglio per la Ricerca e la Sperimentazione in Agricoltura ~ Unità di ricerca per la climatologia e la meteorologia applicate all'agricoltura ~ Rome ~ Italy ^[2]Consiglio per la Ricerca e la Sperimentazione in Agricoltura ~ - Centro di ricerca per lo studio delle relazioni tra pianta e suolo ~ Rome ~ Italy

Bio-physical and socio-economic drivers are at the basis of land degradation (LD) processes. LD of agricultural land implies loss of biological and economic productivity of cropland, rangeland, and woodlands. The combination of these drivers is at the basis of LD vulnerability assessments/indices, such as ESAI (MEDALUS), ESAs (DesertNet), ESI (LADA-FAO), and LVI (CRA-CMA). In ESAI for instance, vulnerability is jointly evaluated through indices of climate, soil, vegetation/land use quality as well as anthropogenic related factors (e.g. population densities and dynamics, level of land management). Land cover and land use (LULC) are essential elements in the assessment. Past changes in LULC can be analysed together with trends of other drivers, in the investigation of LD "syndromes". Climatic forecasts, population projections, as well as GIS based LULC modelling are then used for projecting future trends, providing indications for sustainable management of agricultural land. This paper contains outcomes of the research project AGROSCENARI (Scenarios of agriculture adaptation to climate change), promoted by the Italian Ministry of Agriculture. It aims at investigating syndromes of LD especially in face of climate change in selected regions in the country. The paper focuses on the analysis of LULC time series derived from existing thematic cartography or archive satellite data extracted through procedures developed ad-hoc. Preliminary results in the analysis of changes in LULC and other drivers and related LD syndromes are discussed for the Emilia Romagna region over the period 1954-2008. Also possible scenarios are investigated in respect to the overall vulnerability to LD

LONG-TERM EFFECTS OF GYPSUM, SUGAR FOAM WASTE AND DOLOMITIC ROCK SURFACE INCORPORATED INTO A DEGRADED ACID SOIL ON SOIL ORGANIC CARBON, SOIL CHEMICAL PROPERTIES AND CROP PRODUCTION.

González-Fernández Pedro*^[1], Ordóñez-Fernández Rafaela^[1], Llanos -Triviño Ignacio^[1], Mariscal-Sancho Ignacio^[2], Espejo-Serrano Rafael^[2]

^[1]IFAPA. Centro Alameda del Obispo ~ Recursos Naturales ~ Córdoba ~ Spain ^[2]ETSI Agrónomos. UPM ~ Edafología ~ Madrid ~ Spain

Organic carbon and chemical properties were measured in a degraded acid soil (Plinthic Paleixerult) after 13 years of amended with a single application of several materials: sugar foam waste (E), dolomitic rock (C), gypsum (Y) or dolomitic rock and gypsum mixture (CY). The aim was to evaluate its effects on soil and crops. An application of lime (E or C), equivalent to 6.3 t/ha of calcium carbonate, incorporated into the surface at 0-18 cm was enough to increase the pH in water, from an initial value of 5.08 to 6.3 and to maintain the pH above 5.5 for at least 9 years. The gypsum did not increase the soil residual calcium as had been expected. The cultivated control plots presented the lowest calcium contents in the whole profile sampled. All the liming materials increased the exchangeable calcium in the whole profile. In contrast, the exchangeable magnesium decreased. The cultivated control (O) and Y plots had the lowest levels of magnesium and their exchangeable magnesium became depleted in the 40-80 cm horizon. The continuous cultivation and the initial liming did not significantly diminish the mean organic carbon in the 0-18 cm soil profile (2.53 %) with respect to the natural pasture unaltered plots (F). The mean forage yields harvested in the plots treated with E were significantly superior to the C and CY. The Y and O plots showed very low mean productions and both significantly lower than the rest of the treatments but similar to the F soils (954 kg. d.m./ha).

MAPPING SOIL EROSION RISK AT THE LANDSCAPE SCALE BY ADAPTING THE NATIONAL MODEL MESALES WITH PRECISE SOIL AND AGRONOMICAL INPUT DATA

Lemerancier Blandine*^[2], Jambou Nicolas^[2], Walter Christian^[2]

^[1]Agrocampus Ouest ~ Soil science laboratory ~ Rennes ~ France ^[2]Agrocampus Ouest ~ UMR INRA SAS ~ Rennes ~ France

The MESALES model was developed by Le Bissonnais et al. (2002) to evaluate erosion risk at national scale in France. It combines erosion parameters (land use, crusting, slope, erodibility and climate) into an expert decision tree, to produce an erosion risk level (1 to 5). The objective of this work was to evaluate erosion risk at landscape scale using MESALES and to test the effect of precise input data, notably land use parameter. The study area was a 900ha complex agricultural landscape (NW France), characterized by an oceanic climate, a diversity of soils (Cambisols, Luvisols, Gleysols) developed on granit, schist, metamorphic rocks, deep Aeolian loess and alluvial deposits. The relief is relatively flat except in the zone of contact between granit and schist. Agriculture and land use are dairy production-oriented. Precise data on soils, topography and cultural successions were available, allowing a refinement of MESALES input data without modification on the decision tree. The land use factor was replaced by a number of bare soil days calculated according to observed cultural successions and expert rules on vegetation development. As a result, an estimation of erosion risk was obtained on the studied area, compatible with an aggregation at field level. Improvement of the prediction was mainly due to the slope and land use factors finer resolution. The model can be used to test the effect of climate and/or agricultural practices and land use changes, and could be generalized at regional scale to provide more precise information on soil resource threat.

S03.02-P -27

MAPPING SOIL EROSION RISK USING RUSLE, GIS AND REMOTE SENSING TECHNIQUES

Harb Rabia Ahmed*^[1]

^[1]Faculty of Agriculture, Damanhur Branch, Alexandria University. ~ Department of Natural Resources and Agricultural Engineering ~ Damanhur - Elbehera ~ Egypt

Soil erosion is one of the major causes of land degradation in arid and semi-arid areas like Ethiopia, including Tigray Highlands, which is highly affected by the risk of desertification. Tackling on-site effects of soil erosion requires understanding of the rates of soil loss as well as identification of the major controlling factors that accelerate or slow down these processes. The study aims to quantify the soil loss by erosion process and to specify the main factor affecting the Erosion development in the study area. The Study area was Kilte Awulaelo District which is situated in the eastern part of Tigray region, Ethiopia. Soil erosion models (such as RUSLE) use mathematical expressions to represent the relationships among various factors and processes occurring in the landscape. The RUSLE analysis has been applied to this case study. ArcGIS™ and Excel software were used for all the calculations procedures of RUSLE values and to produce the soil erosion risk map. The final quantitative RUSLE values showed the loss quantity of soil in t/ha/year, ranging from less than 1 to very high soil loss rates (223.6 t/ha/y). The data shows also that Topography (LS) factor was the most effective factor controlling the erosion process followed by the support practices (P) factor. The study showed that stone bands are successful management practice to conquer the soil erosion dilapidations. This study demonstrates that Remote Sensing and GIS are effective tools in generating spatial and quantitative information on soil erosion studies and risk assessment mapping.

**MODELING SOIL EROSION AND RESULTING SEDIMENT DELIVERY TO SURFACE WATERS
AS PRECONDITIONS FOR REGIONAL EROSION CONTROL STRATEGIES**

Schindewolf Marcus^{*[1]}, Jürgen Schmidt^[1], Michael Von Werner^[2]

^[1]TU Bergakademie Freiberg ~ Soil- and Water Conservation Unit ~ Freiberg ~ Germany ^[2]GeoGnostics ~ Soil and Water Conservation ~ Berlin ~ Germany

The process based soil erosion simulation model EROSION 3D is applicated on regional scale for the federal state of Saxony/Germany. This survey is aimed on modeling soil loss, sediment transport and deposition resp. sediment input into surface waters for 10years storm event and three scenarios. The available region-wide geo-data were preprocessed to be used in the parameterization interface DPROC. The core of DPROC is a relational data base consisting of measured or estimated specific model soil parameters. These values have been derived by heavy rainfall simulation experiments below field conditions. The experimental results show a significant relation of soil loss from the mechanical impact due to soil tillage. The regional scale simulations identify the Saxonian Loess Belt as hotspot of soil erosion. However considerable amounts can also be expected in certain areas of the low mountain range. Sediment inputs into surface waters correspond to the hotspots of soil erosion. The amounts of soil losses and sediment inputs could be reduced to 90 % in case of consequently and area-wide transformation to conservation tillage practices. Compared to available model results of USLE and PESERA amounts and distribution of soil losses varies. The differences are caused by different input data and especially by lacking an event based consideration, which disregards system maximal impacts. Since erosion is an exclusive non continuous process, those maximal impacts are highly relevant and have to be considered in case of planning and execution of erosion and water protection concepts.

PEDOGENETIC PROCESSES, SOIL HYDROLOGY AND EROSION ALONG A SOIL CATENA IN THE TURBOLO WATERSHED (NORTHWEST CALABRIA, SOUTHERN ITALY)

Scarciglia Fabio^{*[1]}, Conforti Massimo^[1], Buttafuoco Gabriele^[2], Robustelli Gaetano^[1], Aucelli Pietro P.c.^[3], Palumbo Giuseppe^[4]

^[1]Università della Calabria ~ Dipartimento di Scienze della Terra ~ Arcavacata di Rende (CS) ~ Italy ^[2]CNR ~ Istituto per i Sistemi Agricoli e Forestali del Mediterraneo (ISAFoM) ~ Rende (CS) ~ Italy ^[3]Università di Napoli "Parthenope" ~ Dipartimento di Scienze per l'Ambiente ~ Napoli ~ Italy ^[4]Università del Molise ~ Dipartimento di Scienze Animali, Vegetali e dell'Ambiente ~ Campobasso ~ Italy

This work focuses on the analysis of a soil catena in the Turbolo watershed (NW Calabria, southern Italy), which is representative of widespread zones in this region and in the Mediterranean area, in terms of lithological, geomorphological, pedological and climatic features, and high susceptibility to soil erosion. The Turbolo stream is a left tributary of the Crati river and drains Palaeozoic metamorphic rocks in its western, high-relief, steep sector and Neogene-Quaternary sedimentary terrains in its eastern, hilly, gentler reaches, respectively ranging from about 1015 to 75 m asl. The soil toposequence investigated consists of six soil profiles on an abandoned agricultural land. They developed on Pleistocene marine silty-clays along a N-facing slope, ranging between 85 and 140 m asl in elevation and 5 to 20° inclined, affected by sheet wash, rill and occasional gully erosion. The soil profiles represent Inceptisols with varying juxtaposition of Ap, Bw and Bg horizons, some vertic properties and poor CaCO₃ dynamics. A multidisciplinary approach was applied, spanning from geomorphological and pedological field observations, in situ infiltrometric measurement of hydrological properties, Mercury intrusion porosimetry and chemical-physical laboratory analyses, micromorphological study of thin sections obtained from undisturbed soil samples. The main soil features clearly highlight changes in intensity of major morphodynamic processes along the slope (erosion and reworked soil accumulation), testified by topsoil truncation, varying organic matter and carbonate content. Some interesting relationships are evidenced among particle size distribution, hydraulic conductivity, estimated microporosity, pore size and their effects on water infiltration or runoff and soil erosion.

QUANTIFICATION OF LESSIVAGE IN SOILS: AN EXPERIMENTAL APPROACH

Cornu Sophie^{*[1]}, Quénard Laurence^[2], Samouelian Anatja^[3], Cousin Isabelle^[2]

^[1]INRA ~ UR 1119, GSE ~ Aix en Provence ~ France ^[2]INRA ~ URSOL ~ Orléans ~ France ^[3]INRA ~ LISAH ~ Montpellier ~ France

Lessivage, understood as the vertical transfer of fine particles from a horizon, called eluviated, to another horizon, called illuviated, was never measured to our knowledge due to obvious technical difficulties. Two laboratory experiments focusing respectively on eluviation and on illuviation were designed. Eluviation was experienced on an undisturbed loamy soil column (called L1). Illuviation was experienced on a column made of undisturbed loamy horizon (L1) lying on a second undisturbed monolith of a loamy horizon (called L2) having contrasting mineralogical and physico-chemical properties. For both experiments, rain events of 30 mm were applied with two different intensities: 20 mm/h and 6mm/h. The lower boundary was free drainage during the rain event, and constant pressure head during the infiltration phase. Between two rain events, the soil columns were allowed to dry up in order to recover their initial water content. The water content in the column, the chemistry of the soil solution and the release of particles into the drainage water were monitored. These experiments allowed quantifying eluviation and relating it to preferential drainage, or to the suction applied at the base of the columns and to chemical composition of the soil water. The contribution of these different processes was most probably related to the structure of the soil column. We also determined that 20 to 80 % of the particles released by the L1 horizon were trapped into the L2 horizon allowing for the first time to our knowledge to quantify the intensity of particles fixation in natural soils.

S03.02-P -31

REMOVAL EFFECT OF THE TEPHRA LAYER IN MULCHED IRRIGATED SOILS

Díaz Francisco^[1], Jiménez Concepción^[1], Hernández-Moreno Jose Manuel^[1], Dorta María Ascensión^[1], Tejedor Marisa^[1]

^[1]Universidad de La Laguna ~ Edafología y Geología ~ La Laguna ~ Spain

The “arenados” agrosystem, based on the use of basaltic tephra mulch, has been the means to dryland agriculture in the island of Lanzarote (Canary Islands). The dryland “arenados”, which is a soil and water conservation system, is receding because of the introduction of irrigation thanks to new non-conventional water resources. However, a trend has been observed in some zones to remove the mulch layer in order to improve mechanization. This practice can accelerate soil degradation by low quality irrigation water which is the subject of this study. Two field plots were selected which were formerly covered with a basaltic ash layer and remained uncovered for less than five years. The three key-parameters related to soil degradation in the mulched system: soluble salts, exchangeable sodium percentage, and soluble and sorbed boron, showed a fast increase from three to five years after the ash layer removal. The values reached by these parameters surpassed the recommendable levels for plant toxicity and soil structural degradation. These effects, which in the case of the irrigated, mulched agrosystems appear in the mid- or long term, were reached in a short time interval due to the lack of the positive effect of the mulch in terms of evaporation and salt leaching. The mulch layer removal, therefore, is an unadvisable practice.

S03.02-P -32

RUNOFF, SOIL AND NUTRIENT LOSS VARIABILITY WITHIN AGRICULTURAL LEVELLED PLOTS UNDER HIGH INTENSITY RAINFALL

Ramos Maria Concepción^{*[1]}, Martínez-Casasnovas José Antonio^[1]

^[1]University of Lleida ~ Environment and Soil Science ~ Lleida ~ Spain

Field mechanisation carried out in agricultural systems, which include crops like vineyards, have implied land levelling operations. It introduces high soil and crop variability within the plots and further different responses to soil erosion. The present study analyses soil responses in different parts of a mechanized vineyard in the Penedès region (NE Spain). Soil chemical and physical characteristics were analysed at each location as well as the response to high intensity rainfalls (intensities with 5-year return periods). The study was conducted using a rainfall simulation. Runoff and soil mobilised by runoff were collected at 10-min intervals during one hour or the time needed to reach the steady infiltration rate. The evolution of sediment and P and N concentrations in runoff were analysed. The results point out the variability on erosion rates and nutrient concentration in runoff within the plot. Runoff rates varied between 40.5 and 64.6%, while steady infiltration rate ranged between 28 and 10.3 mm/h. Sediment concentration ranged between 29 and 4.2 g/l, respectively, without significant differences within each simulation. Significant differences were observed in N concentration in runoff, ranging between 45 and 5 mg/l, being higher in the areas where greater sediment concentrations were recorded. P concentration ranged between 1.29 and 2.5 mg/l, being about 90% of total P transported as particulate P. This variability runoff and soil erosion variability is mainly due to the different soil depth and soil characteristics created by land levelling.

S03.02-P -33

SOIL EROSION AND RIVER EXPORTS IN THE LOIRE RIVER BASIN

Gay Aurore^{*[1]}, Olivier Cerdan^[1], Magalie Delmas^[2], Setareh Rad^[3]

^[1]BRGM ~ RIS ~ Orléans ~ France ^[2]INRA ~ INFOSOIL ~ Orléans ~ France ^[3]BRGM ~ GEO ~ Orléans ~ France

Sediment fluxes within continental areas play a major role in the global biogeochemical cycles and are often at the source of soil surface degradation as well as water and ecosystems pollution. In a context where a high proportion of the land surface is experiencing significant land use and climate change, it appears important to be able to carry out local and regional distributed sediment (and associated particles) budgets to assess potential future impacts induced by such changes. Several research efforts have already investigated either global budgets at the river basin or continental scale or local detailed budget at the plot to the field scale. However, very few studies have tried to analyse the connectivity between fluxes and storages and to draw the links between the different scales. In this broad context, the objectives of this study are to investigate what is the fraction of hillslope production which reaches the oceans (is SDR a relevant concept or do we need to identify dominant processes at each different scale?). These investigations will be based on catchments for which mean annual sediment loads are estimated from measurements at their outlet. The characterisation of the basin properties through spatialised approach should be developed to describe the sediment redistribution processes over the drained areas. Based on sediment budget, the source-to-sink dynamic of the sediment cycle can be examined by considering the redistribution processes within the landscape and the rivers networks.

S03.02-P -34

**SOIL EROSION ON NEW CITRUS PLANTATIONS IN EASTERN SPAIN TRIGGER
DESERTIFICATION PROCESSES**

Cerdà Artemi^[1], Giménez Morera Antonio^[2], González Peñolaza Félix Ángel^[3]

^[1]Soil Erosion and Degradation Research Group. Universitat de València, ~ Departament de Geografia ~ Valencia ~ Spain ^[2]Escuela politécnica superior de Alcoy ~ Departamento de Economía y Ciencias Sociales ~ Alcoi ~ Spain ^[3]Soil Erosion and Degradation Research Group. Universitat de València ~ Departament de Geografia ~ Valencia ~ Spain

Citrus plantations in Spain were located on lowland areas such as alluvial plains and terraces in order to allow irrigation by flooding. Citrus production is a two centuries old farming in Eastern Spain and due to the location in the lowest basin position sedimentation was widespread. Since the 80's, an increase in citrus plantations on slope were found due to the use of drip-irrigation systems that now are being used in more than 50 % of the citrus plantations. The traditional tillage management to avoid weeds and the use of herbicides is used also in the slope plantations which results in high erosion rates. Measurements done by means of plots (300 m²) under natural rainfall, and on small plots under simulated rainfall (0.25 to 24 m²) show that soil erosion is extremely high on the new plantations. A survey was done to determine the soil erosion on citrus plantations after the extreme rainfall events of October 2007 and 2008. The results confirm the high erosion rates. Soil fertility is also damaged by the soil losses, and the damage caused by large rainfall events trigger Land Degradation processes. This research was funded by the ENV.2009 243857. Land and Ecosystem Degradation and Desertification: Assessing the Fit of Responses Acronym: LEDDRA Grant agreement No. 243857 CONSORTIUM AGREEMENT and CGL2008-02879/BT.

SOIL INTERRILL ERODIBILITY OF THE SEMI-ARID AREA SOILS: A CASE STUDY IN EAST AZARBAIJAN PROVINCE, IRAN

Ahmadi Abbas*^[1]

^[1]University of Tabriz/ Agriculture Faculty ~ Soil Science ~ Tabriz ~ Iran, Islamic Republic of

Due to climatic, geographical and vegetation conditions of East Azarbaijan Province, the soil of this province have been severely exposed to the interrill erosion. On other hand interrill erodibility factor is one of the most important factors for estimation soil erosion with WEPP model. Therefore it is seem that determination of soil susceptibility to the interrill erosion is necessary. For this reason this study was conducted to determination of soil interrill erodibility in five regions of including: Tabriz plain, Kaleybar, Jolfa and Bonab. Samples from 44 soils series were collected. A rainfall simulator with drainable tilting flume (1 × 0.5 m) at slope of 9% was employed and interrill erodibility factors (K_i) were calculated for 20, 37, and 47 mm h⁻¹ rainfall intensities. Results showed that the K_i value for Kaleybar was significantly less than three other regions and there were no significant difference between the interrill erodibility of Tabriz plain, Jolfa and Bonab regions. Results also showed that organic matter and clay content are two important factors controlling the interrill erodibility and soil erosion rate positively correlated with clay content in these regions.

S03.02-P -36

SOIL –LANDSCAPE RELATIONS IN THE SOUTHWESTERN HIGHLANDS OF UGANDA

Wanyama Wanyama Joshua^[1], Moubax Katrien Moubax^[1], Isabirye Moses Isabirye^[2], Poesen Jean Poesen^[1], Deckers Jozef Deckers^[1]

^[1]Katholieke Universiteit Leuven ~ Department of Earth and Environmental Sciences ~ Leuven ~ Belgium ^[2]Busitema University ~ Natural Resources Management ~ Tororo ~ Uganda

A soil survey was conducted to pin-point the major soil types and to determine their properties in upper Rwizi catchment, south western Uganda. A transect was made through the plateau, hill slope, undulating land and valley bottom. Soil profile description and soil classification were done based on the FAO guidelines and the World Reference Base for Soil Resources respectively. The study shows that in the uplands (1530 – 2170 m a.s.l), the soils are predominantly Plinthosols, Regosols, Leptosols and Cambisols. In the undulating landscape (1480 – 1530 m a.s.l), the soils are predominantly Luvisols and Umbrisols. In the valley bottom (1100 – 1480 m.a.s.l), the soils are predominantly Gleysols and Histosols. Skeletic soils present on the steep slopes are more susceptible to soil erosion and are therefore 'hot spot' areas for application of soil conservation measures. Overall, most soils are acidic, have a moderate CEC and are characterized by an omnipresent depletion of exchangeable base cations. The nutrient depleted nature of the soils reveals an extended period of uncontrolled soil erosion. The soils will only yield good crops under a good management. It is recommended that soil and conservation measures are put in place to ensure sustainable utilization of the soils. Key words: Soil - landscape relation, soil erosion, south western highlands, Uganda

S03.02-P -37

SOIL PROTECTION AND SUSTAINABLE RURAL LAND DEVELOPMENT IN POLAND

Sklodowski Piotr^[1], Szafranek Antoni^[2], Bielska Anna^[2]

^[1]Maria Skłodowska-Curie Warsaw Academy ~ The Faculty of Civil Engineering and Geodesy ~ Warsaw ~ Poland

^[2]Warsaw University of Technology ~ Faculty of Geodesy and Cartography, Department of Spatial Planning and Environmental Sciences ~ Warsaw ~ Poland

The quality of Polish soils belongs to the poorest in Europe. The potential production per hectare of Polish soils has been equal a 0,6 ha potential of arable lands in the European Union. This is a result of the fact that considering the entire area of Poland's arable lands, there are as much as 33% of poor and very poor soils and only 14% high productivity soils. These datas indicate, that with the socioeconomic reasons we have to protect the best productivity soils in Poland first of all. Soil protection laws have formally existed in Poland since 1972. Detailed legal regulations are contained in the Act on Protection of Arable and Forest Land. Its aim the protection of the physical surface of soils. As for December 31. 2010 the size of agricultural lands in Poland equaled to 18.9 million hectares. This results in 0,49 ha per inhabitant. Within the last 50 years, the size of agricultural lands decreased by 2.5 million hectares and the factor per one inhabitant decreased from 0.86 hectare to 0.49 hectare. In the same time the area of forest increased about 10 %. Mainly the poorest soils, formed from sands, permanently dry, were afforested. In next year undoubted are changes in the structure of land use in Poland – the area of agricultural grounds will be diminishing for the benefit of forest are, dwelling areas, communication routes highways, industrial objects and other.

S03.02-P -38

SOIL TEXTURE AS AN INDICATOR OF ENVIRONMENTAL CHANGES IN AGRICULTURAL LANDSCAPE OF NORTH-EASTERN POLAND

Sowinski Pawel^[1], Orzechowski Miroslaw^[1], Smolczynski Slawomir^[1]

^[1]University of Warmia and Mazury in Olsztyn ~ Soil Science and Soil Protection ~ Olsztyn ~ Poland

Morainic landscape of north-eastern Poland has diversified relief. Therefore, it is susceptible to translocation of soil material on the slope. This process, termed anthropogenic denudation, plays a key role in modifying and building landforms and soil cover of agricultural slope landscapes. As a result of long-term agricultural use, arable horizon is translocated and deposited at the bottom of the slope. These processes began in Mazurian Lakeland approximately 4000 years BP. Agricultural human activity changed natural soil cover. The pedotransfer of mineral and organic materials from the top of the slope and their accumulation in land depressions influenced the variability of soil surface horizons. Soil texture is an important indicator of soil cover changes in such diversified areas. As a result of these processes texture of deluvial deposits accumulated at the bottom of the slope and in land depression was changed. The study, using catena method, was carried out in Mazurian Lakeland (north-eastern Poland). Thirty soil profiles were made in typical sites: top, middle part and bottom of the slope as well as in land depression. Soil granular size was analysed using hydrometer method of Bouyoucos, modified by Casagrande and Prószyński, separating sand by sieving. Coefficients of granulation were also calculated, i.e. average size of particles, standard deviation, skewness and kurtosis. The study revealed that the texture of deluvial deposits is a derivative of granular composition of eroded areas. Material accumulated in land depressions was fine-grained and well-sorted. Moreover enrichment in silt and clay was noted.

S03.02-P -39

SPATIAL ANALYSIS OF THE SOIL LOSS FACTORS IN IRRIGATED AREAS OF THE CERRADO REGION OF BRAZIL

Bueno Celia Regina*^[1], Miqueloni Daniela^[1], Quagliariello Vanessa^[1], Cora Jose Eduardo^[1]

^[1]UNESP/FCAV ~ Soil ~ Jaboticabal ~ Brazil

Soil loss is a major problem for agriculture, resulting in reduced productivity and increased costs of production. Thus, the aim of this study was to analyze, by the principal components analysis (PCA) and geostatistics, soil loss due to the loss factors associated with the risk of erosion (RE) and the expected erosion (EE) on a Alfisol and a Oxisol located at Brazil Cerrado Region. The PCA indicated three principal components with 67.2% of the original soil samples variance. In the first principal component (28.9%), the interaction of erosivity and land cover factors are directly related to RE and EE in the upper part of the field. In the second component (22.5%), organic matter shows an inverse interaction with RE and EE on the central part of the field. In the third component (15.8%), management practices factor is inversely related to RE and EE showing areas in the field where the performance is intense in the parts of the field under coffee and beans. The RE was lower on parts of the field (mainly beans) with less than 0.25% of the moderate risk. EE showed that 16.5% of the field is inadequate for management practices and land cover, focusing only in the areas with beans crop, which has greater slope. The results indicated that anthropic factors were the more important soil loss factor in the field, once the soil is well structured, and that the field currently soil management for bean is inadequate.

S03.02-P -40

SPATIAL AND TEMPORAL VARIABILITY OF CO₂ SOIL EMISSION IN A MEDITERRANEAN PEACH ORCHARD

Montanaro Giuseppe^[1], Carelli Silvio^[1], Dichio Bartolomeo^[1], Xiloyannis Cristos^[1]

^[1]Università degli Studi della Basilicata ~ Dipartimento di Scienze dei Sistemi Colturali, Forestali e dell'Ambiente ~ Potenza – Italy

Loss of soil carbon from cultivated land contributes both to soil degradation and global warming. In agroecosystems CO₂ emissions related to fossil fuel energy use are roughly well established, whilst little is known concerning the soil CO₂ emissions at orchards, this hampers development of adequate and environmental friendly policies and orchard management strategies. Therefore, a field trial was conducted in Mediterranean peach orchard in order to explore the seasonal and spatial variations of soil CO₂ flushes. The orchard was managed according to locally conventional practices (i.e. tillage, mineral fertilisation, removal of prunings, drip irrigation). Spatial and temporal variations in CO₂ soil emissions over a 20 m² plot were assessed (LiCor 6400) midday at a 10-15 interval time from January to December. Sampling points (x30) were located at different distances from row line. Soil temperature and moisture were simultaneously assessed. A clear pattern of CO₂ emission rate was detected showing it was at the minimum values of approx. 0.02 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Jan/Dec) and peaked at 0.2 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (end of May) just before the warmer months. Soil CO₂ emissions were mostly from the in-row, with the inter-row emissions being lower, especially due to reduced soil-water content during the drier months. We concluded that spatial variability of emissions must be taken into account if the accuracy of estimates of large-scale emissions are to be improved. Moreover, the need to include CO₂ soil emissions when some CO₂-related parameters (e.g. carbon footprint) are computed is discussed.

S03.02-P -41

STABILIZATION OF SOIL ORGANIC MATTER BY AGGREGATION AND INTERACTIONS WITH MINERALS IS AFFECTED BY SOIL EROSION

Wang Xiang^{*[1]}, Cammeraat Erik^[1], Cerli Chiara^[1], Govers Gerard^[2], Kalbitz Karsten^[1]

^[1]University of Amsterdam ~ Institute for Biodiversity and Ecosystems Dynamics, Earth Surface Science ~ Amsterdam ~ Netherlands ^[2]Katholieke Universiteit Leuven ~ Physical and Regional Geography Research Group ~ Leuven ~ Belgium

Soil erosion and deposition drastically affect the distribution of soil organic carbon within a landscape. Moreover, soil redistribution may have a large impact on the exchange of carbon between the pedosphere and the atmosphere. However, little is known how stabilization of organic matter by aggregation and binding to mineral surfaces is affected by soil redistribution. On topsoil (0–5cm) and subsoil samples (5–10cm, 45–70cm, and 160–200cm) from the Belgium Loess Belt we performed aggregate size distribution and density fractionation, determining carbon and nitrogen content of all the size- and density fractions. Stabilization of organic matter against microbial decay as provided by aggregation was evaluated by a 52-days incubation experiment of entire aggregates (8-16mm) in comparison with crushed ones. In the same experiment we additionally tested the effect of oxygen availability on C mineralization. Further, we analyzed lignin as an important component of soil organic matter in the different soils and soil fractions by the CuO oxidation method. Redistribution of organic carbon resulted in its stabilization as indicated by smaller mineralization at the depositional site in comparison to the eroding site and with increasing soil depth. Aggregation and low O₂ availability resulted in decreased carbon mineralization particularly at the eroding site. Our results suggested that carbon will be transport mainly in the form of aggregates. After deposition, organic carbon will be stabilized against further microbial decay particularly by interaction with soil minerals.

S03.02-P -42

SUBSOIL COMPACTION OF ARABLE LAND IN UPPER AUSTRIA

Murer Erwin*^[1], Baumgarten Andreas^[2], Krammer Carmen^[2]

^[1]Federal Agency for Water Management ~ Land use and land management ~ Petzenkirchen ~ Austria ^[2]Austrian Agency for Health and Food Safety (AGES) ~ Institute for Soil Health and Plant Nutrition ~ Vienna ~ Austria

The objective of this study was to check selected soils in Upper Austria with respect to subsoil compaction. Soil physical investigations were performed at 30 sites representative for the Upper Austrian production area. The sites were selected with respect to the main soil types and the main texture in the subsoil, but not with regard to the soil management. The soil structure was assessed in three categories according to the threshold values of air capacity and saturated hydraulic conductivity. Beneath the plough layer, the subsoil is in critical condition at approximately 30% and in poor condition at 25% of the investigated sites. Statistical analysis showed a significant increase of penetration resistance and subsoil compaction on headland as compared to other parts of the investigated fields. Key words: arable land, subsoil compaction, precompression stress value, penetration resistance, Upper Austria

S03.02-P -43

SUPERFICIAL AND SUBTERRANEAN SOIL EROSION IN TABASCO, TROPICAL MEXICO:

Geissen Violette*^[1], Kampichler Christian^[2], Ochoa Susana^[3], De Jong Ben^[3], Huerta Esperanza^[3], Galindo-acántara Alberto^[2], Daumas Hernandez Salvador^[3]

^[1]Wageningen University and Research Center ~ Alterra-WU-LAD ~ Wageningen ~ Netherlands ^[2]Universidad Juárez Autónoma de Tabasco ~ División Académica de Ciencias Biológicas ~ Villahermosa ~ Mexico ^[3]El Colegio de la Frontera Sur ~ Biodiversidad ~ Villahermosa ~ Mexico

We tried to model superficial and subterranean water erosion based on basic environmental variables such as geological formation, soil type or vegetation cover — data potentially available in developing countries. The study region (3500 km²) located in tropical Mexico we collected data by field observations over the entire study area and elaborated a cartography of different erosion features including data from available maps of geological formation, soil type, precipitation and actual and former land use. Data collected in the field such as vegetation cover and inclination were added. 1039 sites were affected by soil erosion with 2435 single manifestations of soil erosion. 482 sites were found with one gully each, 57 sites with erosion rills with a total of 416, 392 sites with one mass movement each, 85 sites with sinkholes with a total of 1122, and 23 sites with one tunnel each. Rendzic Leptosols over Oligocene limestone are strongly affected by karstification, forming sinkholes and tunnels in regions with inclinations of less than 5°. Superficial erosion features are mainly found on rendzic Leptosols over shale sandstone and on eutric or peli-eutric Vertisols on Andesit in areas with inclinations between 5 and 30°. The application of classification trees allowed to successfully predict the occurrence of sinkholes and tunnels. Predictive success of the occurrence of the different forms of superficial soil losses, however, is low. Nevertheless, automated induction of classification trees can be a valuable tool for preliminary data analysis and hypothesis generation in areas with lack of local expertise

S03.02-P -44

SUSTAINABLE MANAGEMENT OF POTATO ROTATIONS TO MINIMISE SOIL COMPACTION, SURFACE RUNOFF AND DIFFUSE POLLUTION RISK

Silgram Martyn^{*[1]}, Jackson Bob^[1], Wright Philip^[2], Quinton John^[3]

^[1]ADAS UK Ltd., Woodthorne, Wolverhampton, United Kingdom ^[2]Wright Resolutions Ltd., The Spinney, Lincolnshire, United Kingdom ^[3]Lancaster Environment Centre, Lancaster University, Lancaster, United Kingdom

Potato rotations can involve intensive cultivations, parallel beds on raised ridges which channel water, many (>12) passes with spraying and irrigation equipment, and late harvesting when soils are moist. These factors create a high risk of soil compaction, surface runoff, erosion, and diffuse pollution of surface-applied products (irrigation, N, P, pesticides) to surfacewaters. This five-year project investigates practical cost-effective techniques for managing land before, during, and after potatoes to minimize environmental risks on moderately sloping silty clay and loamy sand soils. Novel sample splitters collect runoff from replicated hillslope sections. Before potatoes, treatments included cultivated stubble, stubble with straw, and cover crops. During potatoes, treatments initially focused on losses from stone and no-stone rows, and the impact of spray and irrigation operations on soil and water conditions. Later seasons evaluated novel management techniques with individual and combinations of angled tines both with and without a newly-patented convex surface profiler to alleviate near-surface compaction and direct water back into the crop, compared against tied ridging and control conditions. Results over several site-years reveal over-winter runoff after cereal harvests was greater down wheelings compared to stubble areas, and that cover crops were more effective ($P<0.05$) than stubble at reducing runoff. During potatoes, runoff represented 17.9% of rainfall plus irrigation from stone rows receiving traffic, but only 5.2% from stone rows without traffic and 1.1% from no-stone rows. The angled tine and convex surface profiler both show promise as practical methods to alleviate soil compaction, and reduce runoff and diffuse pollution risk.

TEMPORAL EVOLUTION OF SOIL ERODIBILITY: ASSESSMENT OF EXPLANATORY FACTORS, AND CONSEQUENCES ON EROSION MODELLING. AN EXAMPLE FROM THE BEAUCE AREA, FRANCE.

Algayer Baptiste^{*[1]}, Frédéric Darboux^[1]

^[1]Institut National de Recherche Agronomique (INRA), UR 0272 Science du sol ~ UR 0272 Science du sol ~ Orléans ~ France

Soil erodibility is a key parameter in soil erosion models. Usually, water erosion models take erodibility as a constant for a given soil. However, many studies showed that erodibility changes during the year in relationship with climate. If the seasonal trends are recognized, the underlying factors and processes remain unclear. To assess the climatic parameters and soil properties causing these variations, a six-month long field monitoring was conducted in the Beauce area (south of the Paris Basin, France). Samples from two soils (a silty clay loam and a silt loam) and from two topographic positions were collected at two time scales: monthly, and a few days apart during the week following significant rain events. Aggregate stability was used as a proxy of soil erodibility. Other measurements were humidity and temperature of soil and air, organic matter content, soil texture, water content, microbial biomass, hydrophobicity, and soil crusting. Aggregate stability showed large variability at both time scales. After significant rain events, aggregate stability showed different trends depending on soil type, rain amount and topographic positions. These differences in aggregate stability imply different erodibilities. The results clearly contradict the common practice of assigning a temporally and spatially-constant erodibility to a given soil. Soil texture, organic matter and microbial biomass could not precisely explain erodibility changes. However, the post-rain desiccation was significantly related to the erodibility increase at the short time step. This result emphasizes the influence of the wetting-drying cycles in soil erodibility variation.

TESTING THE “PHYSICAL MODEL CONCEPT” BY SOIL LOSS DATA MEASURED IN SICILY

Bagarello Vincenzo^[1], Ferro Vito^{*[2]}

^[1]University of Palermo ~ SAgA ~ Palermo ~ Italy ^[2]University of Palermo ~ SAgA ~ Palermo ~ Italy

The best possible model to predict the erosion from an area of land has been suggested to be a physical model of the area that has similar soil type, land use, size, shape, slope and erosive inputs. Therefore, a replicated plot has to be considered the best possible, unbiased, real world model. In this paper the physical model concept was tested by using soil loss data collected on plots of different length at the experimental station of Sparacia, in Sicily (South Italy). This investigation supported the conclusions that i) a coefficient of determination between measured and predicted soil loss values of 0.77 has to be considered as the best-case prediction scenario and ii) an uncalibrated deterministic erosion model would not give more accurate results than those obtained by a replicated plot measurement. An effectiveness coefficient of 0.47-0.49 was obtained by applying the original USLE to predict event soil losses at Sparacia. The difference between the value of 0.6, corresponding to what we can expect from an uncalibrated erosion model, and the effectiveness coefficient of the selected model represents the maximum gap that has to be covered to obtain the realistically best estimate of plot soil loss at the event temporal scale.

Agro-ecosystems within Europe are experiencing increased environmental and socio-economic pressures exemplified by intensification of arable farming and increased risk of soil erosion. Arable agro-ecosystems are becoming biologically homogeneous due to farming practice and changes to the seedbank. Specifically, diversity in the weed seedbank has decreased due to the use of herbicides and autumn sown crops (Hawes et al., 2010; Singh and Ghoshal, 2010). Diversity loss has implications for ecosystem resilience and services. Our aim is to investigate the relationships between soil erosion and seed bank dynamics to understand the physical transport processes of weed seeds by water agro-ecosystems. The approach is an experiment field-study at the James Hutton Institute's Balruddery Farm, Scotland, UK . The experiment examines relationships between soil erosion and weed seed redistribution under four tramline treatments. These treatments use different tyre pressures and cultivator tools. A network of 16 gerlach troughs (four treatments in four randomised replicates) was installed at the foot of the tramlines to monitor runoff during rainfall events. Water, sediment and seedbank data were collected after each event. Species data were determined through germination of viable seeds. Seeds were collected after 11 events between November 2010 and April 2011. Over 450 individual seeds were identified along with 21 species. There are statistically significant ($p=0.05$) differences between the treatments for seed mobility in relation to both abundances and species diversity. These results provide novel insights into the structuring role of erosion to influence biodiversity patterns and agro-ecosystem function relating to soil erosion.

THE IMPORTANCE OF ROOTS FOR GULLY EXPANSION IN CEREAL AND OLIVE ORCHARDS

Cammeraat Erik^[1], Pricope Bianca^[1], Vanwalleghem Tom^[2]

^[1]Institute of Biodiversity and Ecosystem Dynamics, Universiteit van Amsterdam ~ Natuurwetenschappen, Wiskunde en Informatica ~ Amsterdam ~ Netherlands ^[2]University of Cordoba ~ Agronomy ~ Cordoba ~ Spain

Gully erosion is now widely recognized as a key process contributing to land degradation, especially in semi-arid areas. However, in spite of numerous studies detailing gully volumes and growth rates, the underlying physical controls are still poorly understood. This study focuses on the interaction between vegetation and gully expansion. It has been observed that many large gullies are stable in length, but keep expanding in width due to sidewall failures. It is analysed how the location and magnitude of these failures is related to the root pattern of olive and cereal crop. We characterized the root distribution by manually counting the roots per diameter class in the field and by determining the root density in the lab. Significant relations with depth and with distance to tree trunk (for the olive orchard) were observed. We measured soil cohesion and root cohesion for each of the diameter classes. The different root cohesion patterns could then be used to explain gully evolution in the two land uses under study: cereal and olive crop.

THE LONG-TERM EFFECTS OF THE SOIL MANAGEMENT IN A TOURISM AREA ON CARBON CONTENT AND MICROBIAL ACTIVITY UNDER A HUMID CLIMATE, NORTH OF IRAN

Khaledian Yones^[1], Kiani Farshad*^[1], Ebrahimi Sohaila^[1]

^[1]Gorgan university of agricultural sciences and natural resources ~ soil science ~ Gorgan ~ Iran, Islamic Republic of

Few studies have focused on the impact of the management regime on the quality of soils in forest and tourism ecosystems. Land use changing by deforestation in northern Iran, has been customary and common especially in Golestan province. This is a crucial factor because in this region, the climatic conditions (especially the plentiful rainfall) affected by erosion development. In this research, the influence in the long-term (50 years) of four types of management (forest, pasture, cultivated, new urban with two geographical aspects) in Ziarat watershed, was evaluated by considering different biochemical and microbiological parameters, including general activity of microbial and carbon content. The study of labile C fractions can be provided important information regarding the metabolic potential of the soil microorganisms. Two-way ANOVA and correlation between soil microbial respiration and Labile carbons showed that organic carbon content significantly increased general microbial activity and carbon fractions. Labile carbons decreased in urban, cultivated and pasture land uses by 87, 66 and 54 % respectively and also non-labile carbons decreased in urban, cultivated and pasture by 76, 49 and 34 % respectively. Soil microbial respiration also decreased in urban, pasture and cultivated that was 0.09, 0.14 and 0.22 mg CO₂/g soil day respectively in comparison with forest that was 0.21. There was no significant difference between the western and northern direction. This study demonstrated that trend of soil degradation and mismanagement caused increasing hazard of urban floods, sediment problem and human health problems due to water pollution in main city of province.

THE MAP OF THE MAXIMUM ADMISSIBLE VALUE OF THE CONSERVATION EFFECT FACTOR OF THE CANOPY COVER AS A TOOL FOR EFFECTIVE WATER EROSION PREVENTION IN THE CZECH REPUBLIC

Vánová Vera^[1], Kristenová Hana*^[1], Smolíková Jana^[1], Novotný Ivan^[1], Pírková Ivana^[1], Žížala Daniel^[1]

^[1]Research Institute for Soil and Water Conservation ~ Department of Soil Service ~ Prague ~ Czech Republic

In the Czech Republic more than 50 % of agricultural land is in risk of water erosion. The main reason of the occurrence of this phenomenon is the land consolidation, disturbance of landscape elements, which started during 1950's in the former Czechoslovakia during communism, and also an inappropriate method of cultivation on arable land (wide-row crops cultivation). Evaluation of erosion processes and their consequences is an important activity of the Research Institute for Soil and Water Conservation. One possible solution, which determines the vulnerability of soil by water erosion, is the map of the Maximum Admissible Value of the Conservation Effect Factor of the Canopy Cover (Cp) which is based on the Universal Soil Loss Equation (USLE). The map is primarily intended to be a basis for a suitable way of farming on the soil blocks or parts of them. The output is raster map which gives information about limit values of Canopy Cover Factor. In case of exceeding the limit value it is necessary to implement the erosion control measures. The map of Cp indicates the limit criteria of Good agricultural and environmental condition (GAEC 2), protects the soil against water erosion and efforts to reduce the negative effects of erosion (flooding, clogging by the washed soil). All the layers of soil and water conservation and the GAEC 2 standard are available to public within the map project "Water and wind erosion of soils CR" at <http://ms.sowac-gis.cz>. Keywords: Soil, Erosion, GAEC 2, Factor of the Canopy Cover

TOWARDS NEW EROSION RISK ASSESSMENT IN NORWAY

Hofmeister Frauke^{*[1]}, Klakegg Ove^[1], Olsen Hilde^[1]

^[1]Norwegian Forest and Landscape Institute ~ Soil resources ~ Ås ~ Norway

The Norwegian Forest and Landscape Institute (NFLI) provides the Norwegian Soil Information System (NSIS), containing detailed soil data classified according to WRB. At present ca. 50% of the total national agricultural area is covered, with main emphasis in the agricultural areas exposed to erosion. The most frequently used thematic map derived from the soil database is the erosion risk map, implemented in 1990. This map is based on USLE adapted to Norwegian conditions using measurements from Norwegian USLE-plots in South-Eastern Norway. Four erosion risk classes are calculated based on soil parameters, slope gradient and standard weather and slope length factors. The most important impact of soil erosion in Norway is the pollution by nutrients of the fresh- and saltwater resources. Regional Agro-Environmental Systems subsidize different sets of measures to reduce the erosion from agricultural areas. Some of these subsidies are graded according to the erosion risk classes. Since the erosion risk map is available on the internet it can easily be used by both farmers and authorities when planning measures, applying for subsidies and allocating payments. The presentation will give an overview of the derivation and use of the erosion risk map. Besides it will present future perspectives on how these maps can be improved. Special focus has the use of better terrain information and the adaption of the model to the Norwegian winter climate. Erosion research during the last centuries and improved and more available weather and terrain (LIDAR) data provide more precise soil erosion maps in the future.
